where $x \in \{0, 1, \ldots, 2^n - 1\}$. This operator is a crucial building block of Shor's Factorization Algorithm. The following example manifests the power of QFT.

Example: Define a function $f : \{0,1,2,3\} \to \{0, \frac{1}{\sqrt{2}}\}$ by $f(1) = f(3) = \frac{1}{\sqrt{2}}$ and $f(0) = f(2) = 0$. This function has period 2. Consider a 2-bit quantum system with state $\frac{1}{\sqrt{2}}(|1\rangle + |3\rangle)$, where the probability amplitudes of the basis states $|0\rangle$, $|1\rangle$, $|2\rangle$, and $|3\rangle$ are specified by the function values of f at 0, 1, 2, and 3. Apply QFT to this state.

$$\begin{aligned}
&\frac{1}{\sqrt{2}}(|1\rangle + |3\rangle) \\
&\quad \to \frac{1}{2\sqrt{2}}(|0\rangle + i|1\rangle - |2\rangle - i|3\rangle) + \frac{1}{2\sqrt{2}}(|0\rangle - i|1\rangle - |2\rangle + i|3\rangle) \\
&\quad = \frac{1}{\sqrt{2}}(|0\rangle - |2\rangle).
\end{aligned}$$

Measurement of the result yields 2, the period of f, with probability $\frac{1}{2}$. Thus, QFT provides a tool for period finding.

In the diagram for QFT, $x_{n-1}x_{n-2}\ldots x_2x_1x_0$ and $y_{n-1}y_{n-2}\ldots y_2y_1y_0$ are the binary representations of x and y, respectively.

74.2 Universal Quantum Gates

Definitions:

A 1-bit gate A is **special** if $\det(A) = 1$.

A 2-bit gate V is **primitive** if V is decomposable, i.e., there exist 1-bit gates S and T such that $V|xy\rangle = S|x\rangle \otimes T|y\rangle$, or $V|xy\rangle = S|y\rangle \otimes T|x\rangle$, for any state $|xy\rangle$.

A 2-bit gate V is **imprimitive** if it is not primitive.

A collection of quantum gates G is **universal** if, for each $n \in \mathbb{N}$, every n-bit quantum gate can be approximated with arbitrary accuracy by a circuit consisting of quantum gates in G.

A collection of quantum gates G is **exactly universal** if, for each $n \in \mathbb{N}$, every n-bit quantum gate can be obtained exactly by a circuit consisting of quantum gates in G.

Facts:

The following facts can be found in [BB02].

1. The collection of all 1-bit gates and any imprimitive 2-bit gate is universal.
2. The collection of all 1-bit gates and any imprimitive 2-bit gate is exactly universal.
3. The collection of all special 1-bit gates and any imprimitive 2-bit gate V with $\det(V)$ not being a root of unity is universal.

Examples:

1. The X_θ, Y_θ, and Z_θ gates are special.
2. The NOT gate and Walsh–Hadamard gate are not special.
3. The 2-bit gate $V = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 \end{bmatrix}$ is primitive, $V|xy\rangle = H|x\rangle \otimes |y\rangle$.
4. The Controlled-NOT gate is imprimitive.
5. The collection of all 1-bit gates and Controlled-NOT gate is universal, and exactly universal.
6. The collection of all X_θ, Y_θ, and Z_θ gates and Controlled-phase gate $\Lambda_1(Q_\theta)$, where $Q_\theta = \begin{bmatrix} 1 & 0 \\ 0 & e^{i\theta} \end{bmatrix}$ and $e^{i\theta}$ is not a root of unity, is universal.

74.3 Deutsch's Problem

Definitions:

A **Boolean function** is a function with codomain $\{0, 1\}$.

A Boolean function $f : \{0,1\} \to \{0,1\}$ is **constant** if $f(0) = f(1)$.

A Boolean function $f : \{0,1\} \to \{0,1\}$ is **balanced** if $f(0) \neq f(1)$.

Problem: Deutsch

Given a Boolean function $f : \{0,1\} \to \{0,1\}$, determine whether it is constant or balanced.

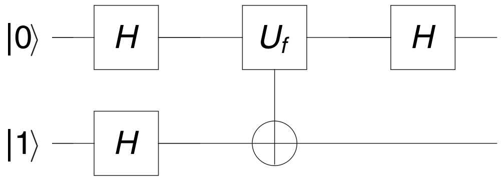
Algorithm: Deutsch

1. Prepare a two-bit quantum register and initialize it to the state $|0\rangle|1\rangle$.
2. Apply the Walsh–Hadamard transform to both qubits.
3. Apply the function evaluation operator U_f

$$U_f : |x\rangle|y\rangle \to |x\rangle|y \oplus f(x)\rangle.$$

4. Apply the Walsh–Hadamard transform to the first qubit.
5. Measure the first qubit. If the outcome is $|0\rangle$, f is constant. If the outcome is $|1\rangle$, f is balanced.

Circuit Diagram: Deutsch



Facts:

The following facts can be found in [CEM98].

1. With the classical computer, we need two evaluations of f to determine whether f is constant or balanced.
2. With the quantum computer, we need only one evaluation of f to determine whether f is constant or balanced.

Examples:

1. Let $f(0) = 0$ and $f(1) = 1$. The following sequence of quantum states shows the result of computation utilizing Deutsch's Algorithm. We start from the initial state $|0\rangle|1\rangle$. Then,

$$\begin{aligned}
&|0\rangle|1\rangle \\
&\to \frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = \frac{|0\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} \\
&\to \frac{|0\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|1\rangle}{\sqrt{2}}\frac{|1\rangle-|0\rangle}{\sqrt{2}} \\
&= \frac{|0\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} - \frac{|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = \frac{|0\rangle-|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} \\
&\to |1\rangle\frac{|0\rangle-|1\rangle}{\sqrt{2}}.
\end{aligned}$$

   The outcome of measuring the first qubit is $|1\rangle$; hence, f is balanced.
2. Let $f(0) = 0$ and $f(1) = 0$. The following sequence of quantum states shows the result of computation utilizing Deutsch's Algorithm. We start from the initial state $|0\rangle|1\rangle$. Then,

$$\begin{aligned}
&|0\rangle|1\rangle \\
&\to \frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = \frac{|0\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} \\
&\to \frac{|0\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = \frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} \\
&\to |0\rangle\frac{|0\rangle-|1\rangle}{\sqrt{2}}.
\end{aligned}$$

   The outcome of measuring the first qubit is $|0\rangle$; hence, f is constant.

74.4 Deutsch–Jozsa Problem

Definitions:

A Boolean function $f : \{0,1\}^n \rightarrow \{0,1\}$ is **constant** if $f(x) = c$, $c \in \{0,1\}$, for all $x \in \{0,1\}^n$.

A Boolean function $f : \{0,1\}^n \rightarrow \{0,1\}$ is **balanced** if the function value is 1 (or 0) for exactly half of the input values, i.e., card $\left(f^{-1}(\{1\})\right) = $ card $\left(f^{-1}(\{0\})\right)$.

Problem: Deutsch–Jozsa

Given a Boolean function $f : \{0,1\}^n \rightarrow \{0,1\}$, which is either constant or balanced, determine whether it is constant or balanced.

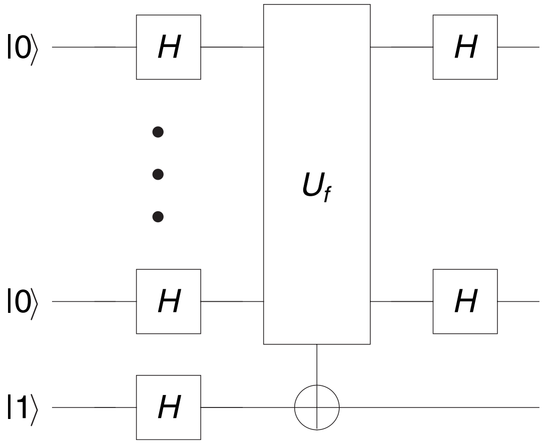
Algorithm: Deutsch–Jozsa

1. Prepare an $(n+1)$-bit quantum register and initialize it to the state $(|0\rangle)^n|1\rangle$.
2. Apply the Walsh–Hadamard transform to all the qubits.
3. Apply the function evaluation operator U_f:

$$U_f : |x\rangle|y\rangle \rightarrow |x\rangle|y \oplus f(x)\rangle.$$

4. Apply the Walsh–Hadamard transform to the first n qubits.
5. Measure the first n qubit. If the outcome is $|00\ldots0\rangle$, f is constant. If the outcome is not $|00\ldots0\rangle$, f is balanced.

Circuit Diagram: Deutsch–Jozsa



Facts:

The following facts can be found in [CEM98].

1. With the classical computer, we need at least $2^{n-1}+1$ evaluations of f to determine with certainty whether f is constant or balanced.
2. With the quantum computer, we need only one evaluation of f to determine with certainty whether f is constant or balanced.

Examples:

1. Let $n = 2$ and $f(00) = f(01) = f(10) = f(11) = 1$. The following sequence of quantum states shows the result of computation utilizing Deutsch–Jozsa's Algorithm. We start from the initial state $|00\rangle|1\rangle$. Then,

$$\begin{aligned}
&|00\rangle|1\rangle\\
&\to \frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = \frac{|00\rangle+|01\rangle+|10\rangle+|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&= \frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&\to \frac{|00\rangle}{2}\frac{|1\rangle-|0\rangle}{\sqrt{2}} + \frac{|01\rangle}{2}\frac{|1\rangle-|0\rangle}{\sqrt{2}} + \frac{|10\rangle}{2}\frac{|1\rangle-|0\rangle}{\sqrt{2}} + \frac{|11\rangle}{2}\frac{|1\rangle-|0\rangle}{\sqrt{2}}\\
&= -\frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} - \frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} - \frac{|10\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} - \frac{|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&= \frac{-|00\rangle-|01\rangle-|10\rangle-|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = -\frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&\to -|00\rangle\frac{|0\rangle-|1\rangle}{\sqrt{2}}.
\end{aligned}$$

   The outcome of measuring the first 2 qubits is $|00\rangle$; hence, f is constant.

2. Let $n = 2$, $f(00) = f(01) = 0$, and $f(10) = f(11) = 1$. The following sequence of quantum states shows the result of computation utilizing Deutsch–Jozsa's Algorithm. We start from the initial state $|00\rangle|1\rangle$. Then,

$$\begin{aligned}
&|00\rangle|1\rangle\\
&\to \frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = \frac{|00\rangle+|01\rangle+|10\rangle+|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&= \frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&\to \frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2}\frac{|1\rangle-|0\rangle}{\sqrt{2}} + \frac{|11\rangle}{2}\frac{|1\rangle-|0\rangle}{\sqrt{2}}\\
&= \frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} - \frac{|10\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} - \frac{|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&= \frac{|00\rangle+|01\rangle-|10\rangle-|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = \frac{|0\rangle-|1\rangle}{\sqrt{2}}\frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&\to |10\rangle\frac{|0\rangle-|1\rangle}{\sqrt{2}}.
\end{aligned}$$

   The outcome of measuring the first 2 qubits is $|10\rangle$; hence, f is balanced.

74.5 Bernstein–Vazirani Problem

Definitions:

Let $x = x_1x_2\ldots x_n$ and $y = y_1y_2\ldots y_n$ be two n-bit strings from $\{0,1\}^n$. The **dot product** $x \cdot y$ is the mod 2 sum of the bitwise products:

$$x \cdot y = x_1y_1 \oplus x_2y_2 \oplus \ldots \oplus x_ny_n.$$

Problem: Bernstein–Vazirani

Given a Boolean function $f_a : \{0,1\}^n \to \{0,1\}$ defined by $f_a(x) = a \cdot x$, where a is an unknown n-bit string in $\{0,1\}^n$, determine the value of a.

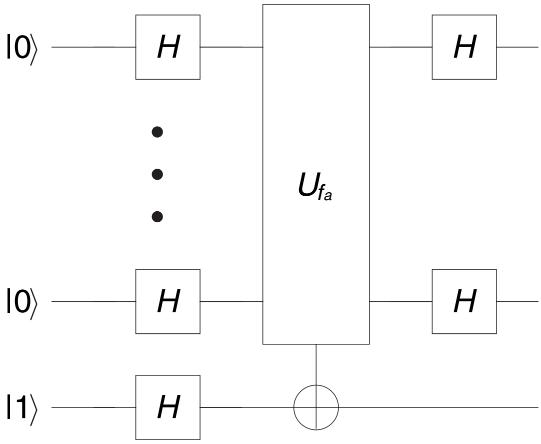
Algorithm: Bernstein–Vazirani

1. Prepare an $(n+1)$-bit quantum register and initialize it to the state $(|0\rangle)^n|1\rangle$.
2. Apply the Walsh–Hadamard transform to all the qubits.
3. Apply the function evaluation operator U_{f_a}:

$$U_{f_a} : |x\rangle|y\rangle \to |x\rangle|y \oplus f_a(x)\rangle.$$

4. Apply the Walsh–Hadamard transform to the first n qubits.
5. Measure the first n qubits. The outcome is $|a\rangle$.

Circuit Diagram: Bernstein–Vazirani



Facts:

The following facts can be found in [BV93].

1. With the classical computer, we need n evaluations of f_a to determine the value of a.
2. With the quantum computer, we need only one evaluation of f_a to determine the value of a.

Examples:

Let $a = 11$, a 2-bit string. The following sequence of quantum states shows the result of computation utilizing Bernstein–Vazirani's Algorithm. We start from the initial state $|00\rangle|1\rangle$. Then,

$$\begin{aligned}
&|00\rangle|1\rangle \\
\to\ & \frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = \frac{|00\rangle+|01\rangle+|10\rangle+|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} \\
=\ & \frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}
\end{aligned}$$

$$
\begin{aligned}
&\to \frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}+\frac{|01\rangle}{2}\frac{|1\rangle-|0\rangle}{\sqrt{2}}+\frac{|10\rangle}{2}\frac{|1\rangle-|0\rangle}{\sqrt{2}}+\frac{|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&=\frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}-\frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}-\frac{|10\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}+\frac{|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&=\frac{|00\rangle-|01\rangle-|10\rangle+|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}}=\frac{|0\rangle-|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}}\\
&\to |11\rangle\frac{|0\rangle-|1\rangle}{\sqrt{2}}.
\end{aligned}
$$

The outcome of measuring the first 2 qubits is $|11\rangle$; hence, $a = 11$.

74.6 Simon's Problem

Definitions:

A function $f : \{0,1\}^n \to \{0,1\}^n$ is 2–1 if for each $z \in \text{range}(f)$, there are exactly two distinct n-bit strings x and y such that $f(x) = f(y) = z$.

A function $f : \{0,1\}^n \to \{0,1\}^n$ has a **period** a if $f(x) = f(x \oplus a)$, $\forall x \in \{0,1\}^n$.

Problem: Simon

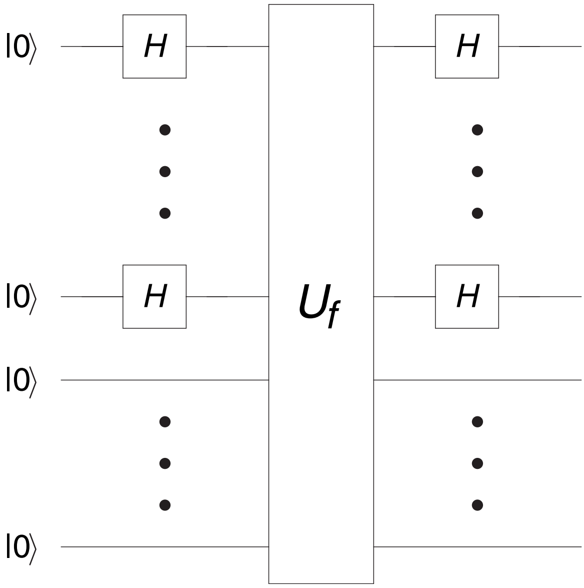
Given a function $f : \{0,1\}^n \to \{0,1\}^n$ which is 2-1 and has period a, determine the period a.

Algorithm: Simon

1. Repeat the following procedure for n times.
   (a) Prepare a $2n$-bit quantum register and initialize it to the state $(|0\rangle)^n(|0\rangle)^n$.
   (b) Apply the Walsh–Hadamard transform to the first n qubits.
   (c) Apply the function evaluation operator U_f:
   $$U_f : |x\rangle|y\rangle \to |x\rangle|y \oplus f(x)\rangle.$$
   (d) Apply the Walsh–Hadamard transform to the first n qubits.
   (e) Measure the first n qubits. Record the outcome $|x\rangle$.
2. With the n outcomes x_1, x_2, …, x_n, solve the following system of linear equations:
$$\begin{cases} x_1 \cdot a = 0 \\ x_2 \cdot a = 0 \\ \quad\vdots \\ x_n \cdot a = 0. \end{cases}$$

   The solution a is the period of f.

Circuit Diagram: Simon



Facts:

The following facts can be found in [Sim94].

1. With the classical computer, we need exponentially many evaluations of f to determine the period a.
2. With the quantum computer, we need $O(n)$ evaluations (on average) of f to determine the period a.

Examples:

Let $f(00) = 01$, $f(01) = 11$, $f(10) = 01$, and $f(11) = 11$. The following sequence of quantum states shows the result of computation utilizing Simon's Algorithm. We start from the initial state $|00\rangle|00\rangle$. Then,

$$
\begin{aligned}
& |00\rangle|00\rangle \\
\to\ & \frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle+|1\rangle}{\sqrt{2}}|00\rangle = \frac{|00\rangle+|01\rangle+|10\rangle+|11\rangle}{2}|00\rangle \\
=\ & \frac{|00\rangle|00\rangle}{2}+\frac{|01\rangle|00\rangle}{2}+\frac{|10\rangle|00\rangle}{2}+\frac{|11\rangle|00\rangle}{2} \\
\to\ & \frac{|00\rangle|01\rangle}{2}+\frac{|01\rangle|11\rangle}{2}+\frac{|10\rangle|01\rangle}{2}+\frac{|11\rangle|11\rangle}{2} \\
=\ & \frac{|00\rangle+|10\rangle}{2}|01\rangle+\frac{|01\rangle+|11\rangle}{2}|11\rangle = \frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle}{\sqrt{2}}|01\rangle+\frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|1\rangle}{\sqrt{2}}|11\rangle \\
\to\ & |0\rangle\frac{|0\rangle+|1\rangle}{2}|01\rangle+|0\rangle\frac{|0\rangle-|1\rangle}{2}|11\rangle = \frac{|00\rangle+|01\rangle}{2}|01\rangle+\frac{|00\rangle-|01\rangle}{2}|11\rangle.
\end{aligned}
$$

The outcome of measuring the first 2 qubits yields either $|00\rangle$ or $|01\rangle$. Suppose that we have run the computation above twice and obtained $|00\rangle$ and $|01\rangle$, respectively. We now have a system of linear equations:

$$\begin{cases} 00 \cdot a = 0 \\ 01 \cdot a = 0. \end{cases}$$

The solution is $a = 10$, the period of this function.

74.7 Grover's Search Algorithm

Problem: Grover

Given an unsorted database with N items, find a target item w. This problem can be formulated using an oracle function $f : \{0, 1, \ldots, N-1\} \to \{0, 1\}$, where

$$f(x) = \begin{cases} 0, & \text{if } x \neq w, \\ 1, & \text{if } x = w. \end{cases}$$

Given such an oracle function, find the w such that $f(w) = 1$.

Algorithm: Grover

Without loss of generality, let $N = 2^n$.

1. Prepare an $(n+1)$-bit quantum register and initialize it to the state $(|0\rangle)^n|1\rangle$.
2. Apply the Walsh–Hadamard transform to all the $n+1$ qubits.
3. Repeat the following procedure for about $\frac{\pi}{4}\sqrt{N}$ times. Cf. Figure 74.1.
    (a) Apply the function evaluation operator U_f (selective sign flipping operator):

    $$U_f : |x\rangle|y\rangle \to |x\rangle|y \oplus f(x)\rangle.$$

    This is equivalent to the unitary operator $\mathcal{I}_w = I - 2|w\rangle\langle w|$ on the first n qubits.

    (b) Apply unitary operator (inversion about the average operator) $\mathcal{I}_s = 2|s\rangle\langle s| - I$ on the first n qubits. Cf. Figure 74.2.
4. Measure the first n qubits. We obtain the search target with high probability.

Facts:

1. [Gro97] With the classical computer, on average, we need $O(N)$ oracle calls (evaluations of f) to find the search target.
2. [Gro97] With the quantum computer, on average, we need $O(\sqrt{N})$ oracle calls to find the search target.

Circuit Diagrams: Grover

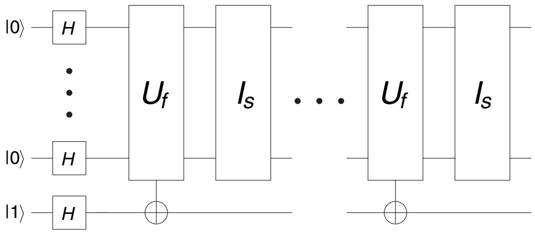


FIGURE 74.1 Grover's Algorithm.

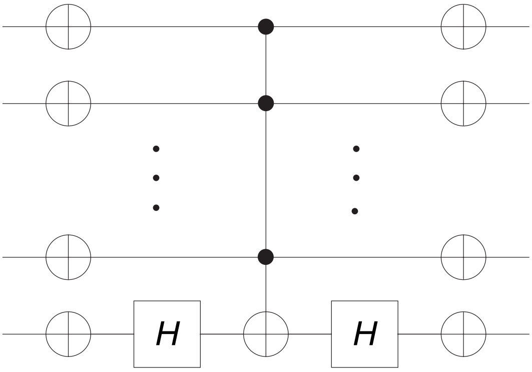

FIGURE 74.2 Inversion about the average operator $\mathcal{I}_s$.

3. [BBH98] When $N = 4$, using Grover's Algorithm, exactly one oracle call suffices to find the search target with certainty.
4. [Dia10] Excluding the trivial case of $N = 1$, $N = 4$ is the only case to find the search target with certainty using Grover's Algorithm.

Examples:

Let $N = 2^2 = 4$ and Item 3 be the search target, which is encoded by the quantum state $|11\rangle$ (11 is the binary representation of 3). The following sequence of quantum states shows the result of computation utilizing Grover's Algorithm. We start from the initial state $|00\rangle|1\rangle$. Then,

$$\begin{aligned}
&|00\rangle|1\rangle \\
\to\ & \frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle+|1\rangle}{\sqrt{2}}\frac{|0\rangle-|1\rangle}{\sqrt{2}} = \frac{|00\rangle+|01\rangle+|10\rangle+|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} \\
=\ & \frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} \\
\to\ & \frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|11\rangle}{2}\frac{|1\rangle-|0\rangle}{\sqrt{2}} \\
=\ & \frac{|00\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|01\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} + \frac{|10\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} - \frac{|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} \\
=\ & \frac{|00\rangle+|01\rangle+|10\rangle-|11\rangle}{2}\frac{|0\rangle-|1\rangle}{\sqrt{2}} \\
\to\ & |11\rangle\frac{|0\rangle-|1\rangle}{\sqrt{2}}.
\end{aligned}$$

The outcome of measuring the first 2 qubits yields $|11\rangle$, which is the search target $w = 3$.

Comments:

Grover's Algorithm was discovered by L.K. Grover of Bell Labs in 1996. This algorithm provides a quadratic speedup over classical algorithms. Although it is not exponentially fast (as Shor's Algorithm is), it has a wide range of applications. It could be used to accelerate any algorithms related to searching an unsorted database, including quantum database search, finding the solution of NP problems, finding the median and minimum of a data set, and breaking the Data Encryption Standard (DES) cryptography system.

74.8 Shor's Factorization Algorithm

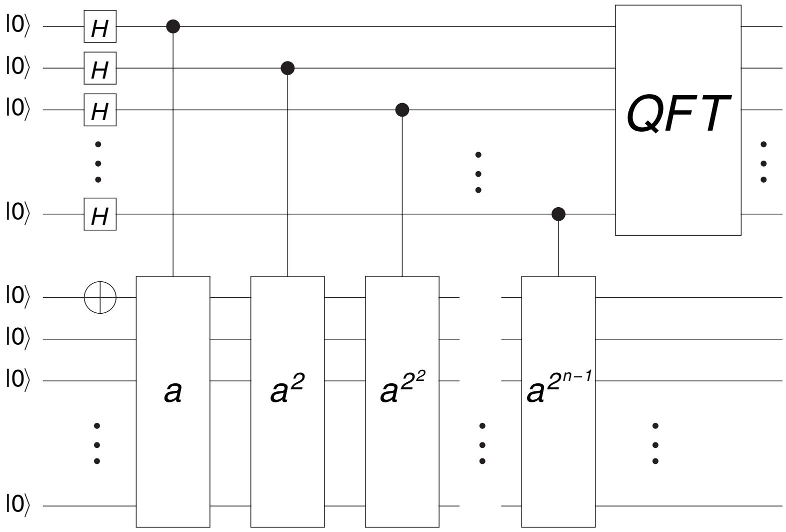
Integer Factorization Problem:

Given a composite positive integer N, factor it into the product of its prime factors.

Algorithm: Shor

1. Choose a random number $a < N$; make sure that a and N are coprime. This can be done by using a random number generator and Euclidean algorithm on a classical computer.
2. Find the period T of function $f_{a,N}(x) = a^x \quad mod \quad N$. This step can be further expanded as follows:
   (a) Prepare two L-bit quantum registers in initial state
   $$\left(\frac{1}{\sqrt{2^L}}\sum_{x=0}^{2^L-1}|x\rangle\right)|0\rangle,$$
   where L is chosen such that $N^2 \leq 2^L < 2N^2$.
   (b) Apply the function evaluation operator $U_f : |x\rangle|0\rangle \to |x\rangle|f_{a,N}(x)\rangle$:
   $$\frac{1}{\sqrt{2^L}}\sum_{x=0}^{2^L-1}|x\rangle|0\rangle \to \frac{1}{\sqrt{2^L}}\sum_{x=0}^{2^L-1}|x\rangle|f_{a,N}(x)\rangle.$$
   (c) Apply QFT to the first register:
   $$\frac{1}{\sqrt{2^L}}\sum_{x=0}^{2^L-1}|x\rangle|f_{a,N}(x)\rangle \to \frac{1}{2^L}\sum_{y=0}^{2^L-1}\left(\sum_{x=0}^{2^L-1}e^{2\pi ixy/2^L}|y\rangle\right)|f(x)\rangle.$$
   (d) Make a measurement on the first register, obtaining y.
   (e) Find T from y via the continued fraction for $\frac{y}{2^L}$. This step might fail; in that case, repeat from 2a.
3. If T is odd, repeat from Step 1. If T is even and $N \mid (a^{T/2}+1)$, repeat from Step 1. If T is even and $N \nmid (a^{T/2}+1)$, compute $d = gcd(a^{T/2}-1, N)$, which is a nontrivial factor of N.

Circuit Diagrams: Shor



Facts:

The following facts can be found in [Sho94].

1. The integer factorization problem is classically *intractable*. The most efficient classical algorithm to date, a *number field sieve*, has a time complexity of $O(\exp{(\log N)^{1/3}}(\log\log N)^{2/3})$.
2. Shor's quantum factorization algorithm has a time complexity of $O((\log N)^2 \log\log N \log\log\log N)$. Hence, it is a polynomial time algorithm.

Examples:

Let $N = 15$. Choose $L = 8$ such that $N^2 = 225 < 2^L < 450 = 2N^2$. Choose a random integer $a = 2$, which is coprime with 15. Thus, $f_{a,N}(x) = 2^x \bmod 15$. The following sequence of quantum states shows the result of computation utilizing Shor's Algorithm:

$$
\begin{aligned}
|0\rangle|0\rangle &\rightarrow \frac{1}{2^4}\sum_{x=0}^{2^8-1}|x\rangle|0\rangle \\
&\rightarrow \frac{1}{2^4}\sum_{x=0}^{2^8-1}|x\rangle|f_{a,N}(x)\rangle \\
&= \frac{1}{2^4}(|0\rangle|1\rangle + |1\rangle|2\rangle + |2\rangle|4\rangle + |3\rangle|8\rangle \\
&+ |4\rangle|1\rangle + |5\rangle|2\rangle + |6\rangle|4\rangle + |7\rangle|8\rangle + \cdots + |2^8-2\rangle|4\rangle + |2^8-1\rangle|8\rangle) \\
&\rightarrow \frac{1}{2^4}\sum_{x=0}^{2^8-1}\frac{1}{2^4}\sum_{y=0}^{2^8-1}\omega^{xy}|y\rangle|2^x \bmod 15\rangle \\
&\rightarrow \frac{1}{2^8}\sum_{y=0}^{2^8-1}|y\rangle\sum_{x=0}^{2^8-1}\omega^{xy}|2^x \bmod 15\rangle,
\end{aligned}
$$

where $\omega = e^{2\pi i/2^8}$. Suppose that the outcome of measuring the first n qubits is $|56\rangle$. We can compute the continued fraction of $\frac{56}{256}$ to be $[0, 4, \ldots]$. The second number 4 satisfies $2^4 = 1 \bmod 15$. So 4 is the period of $f_{a,N}$. $2^{4/2} - 1 = 3$ yields a factor of 15 and $15 = 3 \times 5$.

Comments:

Shor's Algorithm was discovered by P. Shor of AT&T Labs in 1994. It is the most important breakthrough in the research of quantum computation thus far. It solves the integer factorization problem, an extremely hard problem for classical computers, in polynomial time. The security of the RSA cryptographic system, which is widely used nowadays over the Internet, is based on the difficulty of factoring large integers. Equipped with a quantum computer, one could easily break the RSA codes with Shor's Algorithm.

A major challenge to information processing is to protect the information from noise in the external environment. Quantum error correction (QEC) is used in quantum computing to protect quantum information from errors due to decoherence and other quantum noise. In this chapter, we give an introduction to the operator theoretic approach to quantum error correction. One may see [Gai08, NC00] for some general background of QEC, and an algebraic approach to QEC. Information on quantum computing can be found in Chapter 74.

75.1 Basic Concepts

Definitions:

In the Hilbert space model of quantum mechanics, the **vector states** of a **quantum system** with n physical measurable states are represented by **unit column vectors** $|x\rangle$ in $\mathbb{C}^n$. See Section 5.1 for the definition and basic properties of a Hilbert space.

Several quantum systems can form a **composite system**; its vector states are the tensor products of the vector states of its **subsystems**: $|x_1\rangle \otimes \cdots \otimes |x_m\rangle$, abbreviated as $|x_1 \cdots x_m\rangle$, if the meaning is clear in the context.

In quantum information science, one often uses vector states $|x\rangle \in \mathbb{C}^2$. The two **measurable states** are $|0\rangle = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$ and $|1\rangle = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$. The vector state $|x\rangle = a|0\rangle + b|1\rangle = \begin{bmatrix} a \\ b \end{bmatrix}$ with $|a|^2 + |b|^2 = 1$ is said to be in **superposition** of the states $|0\rangle$ and $|1\rangle$. Therefore, a unit vector in $\mathbb{C}^2$ represents a basic unit known as a **quantum bit** (abbreviated as **qubit**) of quantum information.

If $|x_1\rangle = \begin{bmatrix} a \\ b \end{bmatrix}$ and $|x_2\rangle = \begin{bmatrix} c \\ d \end{bmatrix}$ are vector states in $\mathbb{C}^2$, then

$$|x_1 x_2\rangle = \begin{bmatrix} a \\ b \end{bmatrix} \otimes \begin{bmatrix} c \\ d \end{bmatrix} = \begin{bmatrix} ac \\ ad \\ bc \\ bd \end{bmatrix}$$

is a **tensor state in the composite system** $\mathbb{C}^2 \otimes \mathbb{C}^2$. (See Section 11.4 for the definition of Kronecker tensor product).

Examples:

1. If $|0\rangle$ and $|1\rangle$ represent the measurable vector states in $\mathbb{C}^2$, then
$$\{|00\rangle, |01\rangle, |10\rangle, |11\rangle\} = \left\{ \begin{bmatrix}1\\0\\0\\0\end{bmatrix}, \begin{bmatrix}0\\1\\0\\0\end{bmatrix}, \begin{bmatrix}0\\0\\1\\0\end{bmatrix}, \begin{bmatrix}0\\0\\0\\1\end{bmatrix} \right\}$$
is the set of the four measurable states in $\mathbb{C}^2 \otimes \mathbb{C}^2$. A general vector state in the composite system is represented by a unit vector in $\mathbb{C}^4$.
2. In a composite system of n-qubits, there are $N = 2^n$ measurable states, and a general vector state is a unit vector in $\mathbb{C}^N$.

75.2 Quantum Error Correction with Syndrome Measurement

To protect the integrity of the information, quantum information is encoded in some qubits before transmission. When the information is received, we can perform a multi-qubit measurement (syndrome measurement) to determine if (and how) a qubit has been corrupted. Then we can apply a quantum operation to reverse the effect of the error.

Examples:

1. (*Three-Qubit Bit-Flip Quantum Error Correction Code*) Suppose that qubits are transmitted through a channel such that a qubit $|\psi\rangle$ may change to $X|\psi\rangle$ with probability $p \in (0, 1)$, where $X = \begin{bmatrix}0 & 1\\1 & 0\end{bmatrix}$. In particular, $|0\rangle$ and $|1\rangle$ may be erroneously transmitted as $|1\rangle$ and $|0\rangle$, respectively. This is known as a bit-flip error. One may use the following QEC scheme.

   Step 1 *Encoding.* Encode the one-qubit information $|x\rangle = a|0\rangle + b|1\rangle$ by
$$|x\rangle = a|0\rangle + b|1\rangle \mapsto |\phi\rangle = a|000\rangle + b|111\rangle.$$
   So, a unit vector $|x\rangle = \begin{bmatrix}a\\b\end{bmatrix}$ is encoded as $|\phi\rangle = ae_1 + be_8$ in $\mathbb{C}^8$, where $\{e_1, \ldots, e_8\}$ represents the standard basis for $\mathbb{C}^8$.

   Step 2 *Transmission.* Assume that the only error that can occur to each qubit is of the form
$$\alpha|0\rangle + \beta|1\rangle \mapsto X(\alpha|0\rangle + \beta|1\rangle) = \alpha|1\rangle + \beta|0\rangle \quad \text{with} \quad X = \begin{bmatrix}0 & 1\\1 & 0\end{bmatrix}.$$
   In other words, if a tensor state $|y_1\, y_2\, y_3\rangle$ is sent, and the tensor state $|z_1\, z_2\, z_3\rangle$ is received, then for each $i = 1, 2, 3$, there is a probability p that $|z_i\rangle = X|y_i\rangle$ and a probability $(1 - p)$ that $|z_i\rangle = |y_i\rangle$.

   Step 3 *Error syndrome detection and correction.* From the received state $|\psi\rangle = |z_1\, z_2\, z_3\rangle$, construct the syndrome
$$|z_4\, z_5\rangle = |z_1 +_2 z_2\rangle|z_1 +_2 z_3\rangle,$$
   where $+_2$ is the modulo 2 addition. We then apply one of the following corrections.

(a) If $|z_4\, z_5\rangle = |00\rangle$, do nothing.

(b) If $|z_4\, z_5\rangle = |11\rangle$, apply $X_1 = X \otimes I \otimes I$ to $|\psi\rangle$.

(c) If $|z_4\, z_5\rangle = |10\rangle$, apply $X_2 = I \otimes X \otimes I$ to $|\psi\rangle$.

(d) If $|z_4\, z_5\rangle = |01\rangle$, apply $X_3 = I \otimes I \otimes X$ to $|\psi\rangle$.

If the probability of error p is less than $\frac{1}{2}$, then there is a higher chance, namely, $(1-p)^2(1+2p)$, for the resulting vector to be equal to $|\phi\rangle$, as shown in the following table. For more details, see, e.g., [NO08].

Received state	Syndrome	Decoded state	Probability
$a\|000\rangle + b\|111\rangle$	$\|00\rangle$	$a\|000\rangle + b\|111\rangle$	$(1-p)^3$
$a\|100\rangle + b\|011\rangle$	$\|11\rangle$	$a\|000\rangle + b\|111\rangle$	$(1-p)^2p$
$a\|010\rangle + b\|101\rangle$	$\|10\rangle$	$a\|000\rangle + b\|111\rangle$	$(1-p)^2p$
$a\|001\rangle + b\|110\rangle$	$\|01\rangle$	$a\|000\rangle + b\|111\rangle$	$(1-p)^2p$
$a\|110\rangle + b\|001\rangle$	$\|01\rangle$	$a\|111\rangle + b\|000\rangle$	$(1-p)p^2$
$a\|101\rangle + b\|010\rangle$	$\|10\rangle$	$a\|111\rangle + b\|000\rangle$	$(1-p)p^2$
$a\|011\rangle + b\|100\rangle$	$\|11\rangle$	$a\|111\rangle + b\|000\rangle$	$(1-p)p^2$
$a\|111\rangle + b\|000\rangle$	$\|00\rangle$	$a\|111\rangle + b\|000\rangle$	p^3

75.3 Operator Quantum Error Correction

From an observational point of view, a state $|\psi\rangle$ cannot be distinguished from $e^{i\theta}|\psi\rangle$ for any global phase factor $e^{i\theta}$. Therefore, we can represent the state $|\psi\rangle$ by the matrix $|\psi\rangle\langle\psi|$, where $\langle\psi| = |\psi\rangle^*$.[1] Thus, a unitary transform $U : |\psi\rangle \mapsto U|\psi\rangle$ corresponds to the unitary similarity $|\psi\rangle\langle\psi| \mapsto U|\psi\rangle\langle\psi|U^*$. We extend these ideas in the Definitions. Additional connections are provided by the Facts.

Definitions:

In quantum information, **quantum states** with n physical measurable states are represented by $n \times n$ **density matrices**, i.e., $n \times n$ positive semidefinite matrices with trace one.

A **quantum channel (operation)** is a linear operator Φ on $\mathbb{C}^{n\times n}$, which admits the following operator sum representation

$$\Phi(A) = \sum_{j=1}^{r} F_j A F_j^*, \tag{75.1}$$

where $F_1, \ldots, F_r \in \mathbb{C}^{n\times n}$ satisfy $\sum_{j=1}^{r} F_j^* F_j = I_n$. In the context of quantum error correction, $F_1, \ldots, F_r$ are called the **error operators**, which represent decoherence and quantum noise.

A subspace V of $\mathbb{C}^n$ is called a **quantum error-correction code (QECC)** of a quantum channel Φ on $\mathbb{C}^{n\times n}$ if there exists a quantum channel Ψ on $\mathbb{C}^{n\times n}$ such that $(\Psi \circ \Phi)(A) = A$ for all density matrices A satisfying $PAP = A$, where P is the orthogonal projection of $\mathbb{C}^n$ onto V. Ψ is called a **recovery channel** for Φ.

Suppose a quantum channel Φ has a non-trivial quantum error-correction code V of dimension k. Let $\mathcal{C}$ be the set of matrices A satisfying $PAP = A$. Then $\mathcal{C}$ is isomorphic to $\mathbb{C}^{k\times k}$. We can **encode** a $k \times k$ density matrix $\tilde{A}$ into an $n \times n$ density matrix $A \in \mathcal{C}$ by an isomorphism $\tilde{A} \to W\tilde{A}W^*$, where $W = [\mathbf{w}_1 \ \cdots \ \mathbf{w}_k]$ with $\{\mathbf{w}_1, \ldots, \mathbf{w}_k\}$ an orthonormal basis for V.

---

[1] Here X^* denotes the conjugate transpose of X, which is the same as $X^\dagger$ in physics notation.

Facts:

1. For any state $|\psi\rangle \in \mathbb{C}^n$, $|\psi\rangle\langle\psi|$ is an $n \times n$ density matrix.
2. $|\psi\rangle\langle\psi| = |\varphi\rangle\langle\varphi|$ if and only if $|\varphi\rangle = e^{i\theta}|\psi\rangle$ for some θ.
3. Let $F_1, \ldots, F_r \in \mathbb{C}^{n\times n}$ satisfy $\sum_{j=1}^{r} F_j^* F_j = I_n$. Then $\operatorname{tr}\left(\sum_{j=1}^{r} F_j A F_j^*\right) = \operatorname{tr} A$, so $\Phi(A) := \sum_{j=1}^{r} F_j A F_j^*$ maps a density matrix to a density matrix.

Examples:

1. (*Three-Qubit Bit-Flip Quantum Error Correction Code*) A *bit flip* on one qubit is represented by $A \mapsto XAX^*$ with $X = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$. Recall that for the tensor product $A_1 \otimes A_2$ of two operators A_1 and A_2, $(A_1 \otimes A_2)(\mathbf{x}_1 \otimes \mathbf{x}_2) = (A_1\mathbf{x}_2) \otimes (A_2\mathbf{x}_2)$ (see Fact 11.4.11). Let $X_0 = I_2 \otimes I_2 \otimes I_2 = I_8$, $X_1 = X \otimes I_2 \otimes I_2$, $X_2 = I_2 \otimes X \otimes I_2$, and $X_3 = I_2 \otimes I_2 \otimes X$. For example,

$$X_2 = I_2 \otimes X \otimes I_2 = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \end{bmatrix}.$$

Consider the quantum channel $\Phi : \mathbb{C}^{n\times n} \to \mathbb{C}^{n\times n}$ defined by

$$\Phi(A) = \sum_{j=0}^{3} p_j X_j A X_j^*,$$

where $p_j \geq 0$ and $\sum_{j=0}^{3} p_j = 1$. Then Φ represents a channel on three qubits with a probability of p_j that the j^{th} qubit will be flipped. Let $P = |000\rangle\langle 000| + |111\rangle\langle 111|$. Then the recovery channel Ψ is given by

$$\Psi(B) = \sum_{j=0}^{3} P X_j^* B X_j P \tag{75.2}$$

with the 2-dimensional quantum error-correction code spanned by $\{|000\rangle, |111\rangle\}$.

75.4 Knill-Laflamme Theorem and Higher Rank Numerical Ranges

The Knill-Laflamme Theorem gives conditions on when a subspace V is a quantum error-correction code for a quantum channel; see [Gai08, KL97, NC00]. Motivated by condition (75.3) in the Knill-Laflamme Theorem (see the details in the following Facts), researchers (see [CKZ06, LPS09, LS08]) have studied the concepts defined next, including the higher rank numerical range.

Definitions:

Let $\mathbf{A} = (A_1, \ldots, A_m)$, where $A_1, \ldots, A_m \in \mathbb{C}^{n\times n}$. The **higher rank numerical range** $\Lambda_k(\mathbf{A})$ [CKZ06, LPS09, LS08] is the set of $(a_1, \ldots, a_m) \in \mathbb{C}^m$ such that for some rank-k orthogonal projection P,

$$PA_jP = a_jP, \qquad j = 1, \ldots, m.$$

Facts: Let $\mathbf{A} = (A_1, \ldots, A_m)$, where $A_1, \ldots, A_m \in \mathbb{C}^{n\times n}$.

1. (*Knill-Laflamme Theorem*) [Gai08, KL97, NC00] Let $\Phi : \mathbb{C}^{n\times n} \to \mathbb{C}^{n\times n}$ be a quantum channel of the form (75.1). Suppose $V \subseteq \mathbb{C}^n$ is a subspace and $P_V \in \mathbb{C}^{n\times n}$ is the orthogonal projection with V as the range space. Then V is a quantum error-correction code if and only if there are scalars $\gamma_{ij} \in \mathbb{C}$ with $1 \le i, j \le r$ such that
$$P_V F_i^* F_j P_V = \gamma_{ij} P_V, \quad 1 \le i, j \le r. \tag{75.3}$$
2. Let $\Phi : \mathbb{C}^{n\times n} \to \mathbb{C}^{n\times n}$ be a quantum channel of the form (75.1). Then Φ has a k-dimensional quantum error-correction code if and only if
$$\Lambda_k\left(F_1^*F_1, F_1^*F_2, \ldots, F_r^*F_r\right) \neq \emptyset.$$
3. $(a_1, \ldots, a_m) \in \Lambda_k(\mathbf{A})$ if and only if there is a unitary $U \in \mathbb{C}^{n\times n}$ such that the leading $k \times k$ principal submatrix of U^*A_jU equals a_jI_k for $j = 1, \ldots, m$.
4. $(a_1, \ldots, a_m) \in \Lambda_k(\mathbf{A})$ if and only if there exists $X \in \mathbb{C}^{n\times k}$ such that $X^*X = I_k$ and
$$X^*A_jX = a_jI_k, \quad j = 1, \ldots, m.$$
5. [KLV00, LP11, LPS09] Let $A_1, \ldots, A_m$ be $n \times n$ Hermitian matrices and $k > 1$.
    (a) If $n \ge (k-1)(m+1)^2$, then $\Lambda_k(A_1, \ldots, A_m) \neq \emptyset$.
    For $m = 1, 2$, the bound in (a) can be further improved as follows.
    (b) If $n \ge 2k - 1$, then $\Lambda_k(A_1) \neq \emptyset$.
    (c) If $n \ge 3k - 2$, then $\Lambda_k(A_1, A_2) \neq \emptyset$.
    The bounds in (b) and (c) are best possible.
6. [LPS09] Let $\Phi(A) = pU_1AU_1^* + (1-p)U_2AU_2^*$, with $0 < p < 1$ and unitary U_1, $U_2 \in \mathbb{C}^{n\times n}$, $n \ge 4$. Then Φ has a QECC of dimension 2.

Examples:

1. Consider the bi-unitary channel $\Phi : \mathbb{C}^{4\times 4} \to \mathbb{C}^{4\times 4}$ given by
$$\Phi(A) = pA + (1-p)UAU^*,$$
where U is the diagonal matrix with diagonal $(1, i, -1, -i)$ and $0 < p < 1$. In other words,
$$\Phi(A) = F_1AF_1^* + F_2AF_2^*$$
with $F_1 = \sqrt{p}I_4$ and $F_2 = \sqrt{1-p}U$. Let V be the subspace spanned by the vectors
$$|00\rangle + |10\rangle = \begin{bmatrix}1\\0\\1\\0\end{bmatrix} \qquad \text{and} \qquad |01\rangle + |11\rangle = \begin{bmatrix}0\\1\\0\\1\end{bmatrix}.$$

Then we have

$$P_V F_i^* F_j P_V = \gamma_{ij} P_V, \quad 1 \le i, j \le 2,$$

where $\gamma_{11} = p$, $\gamma_{22} = 1 - p$, and $\gamma_{12} = \gamma_{21} = 0$. Therefore, the conditions in Eq. (75.3) are satisfied. The recovery channel Ψ is given by

$$\Psi(A) = \sum_{j=1}^{2} G_j A G_j^*$$

where

$$G_1 = \frac{1}{2}\begin{bmatrix} 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & 1 & 0 \\ 0 & 1 & 0 & 1 \end{bmatrix} \qquad \text{and} \qquad G_2 = \frac{1}{2}\begin{bmatrix} 1 & 0 & -1 & 0 \\ 0 & -i & 0 & i \\ 1 & 0 & -1 & 0 \\ 0 & -i & 0 & i \end{bmatrix}.$$

75.5 Decoherence Free Subspace, Noiseless Subsystem, and Correctable Subsystem

Decoherence free subspace, noiseless subsystem, and correctable subsystem are three standard methods to correct collective errors; see [KL97, KLP06].

Definitions:

Let Φ be a quantum channel on $\mathbb{C}^{n\times n}$.

A subspace V of $\mathbb{C}^n$ is said to be a **decoherence free subspace (DFS)** for Φ if

$$\Phi(A) = A \quad \text{for all} \quad A \in \mathbb{C}^{n\times n} \text{ satisfying } A = P_V A P_V, \tag{75.4}$$

where P_V is the orthogonal projection of $\mathbb{C}^n$ onto V.

For a Hilbert space $\mathcal{H}$, let $B(\mathcal{H})$ denote the bounded linear operators on $\mathcal{H}$. If $\dim \mathcal{H} = n$, then $\mathcal{H}$ and $B(\mathcal{H})$ can be represented by $\mathbb{C}^n$ and $\mathbb{C}^{n\times n}$, respectively. Suppose the Hilbert space $\mathcal{H}$ has a decomposition $\mathcal{H} = (\mathcal{H}^A \otimes \mathcal{H}^B) \oplus \mathcal{K}$ for some Hilbert spaces $\mathcal{H}^A$, $\mathcal{H}^B$, and $\mathcal{K}$. For $A \in B(\mathcal{H}^A)$ and $B \in B(\mathcal{H}^B)$, define $A \otimes B$ on $\mathcal{H}$ by

$$(A \otimes B)(\mathbf{x} \otimes \mathbf{y} \oplus \mathbf{z}) = A\mathbf{x} \otimes B\mathbf{y} \oplus 0_{\mathcal{K}},$$

where $\mathbf{x} \in \mathcal{H}^A$, $\mathbf{y} \in \mathcal{H}^B$, and $\mathbf{z} \in \mathcal{K}$. Here $0_{\mathcal{K}}$ represents the zero vector in $\mathcal{K}$.

Suppose Φ is a quantum channel on $\mathcal{H}$ such that $\mathcal{H}$ has a decomposition $\mathcal{H} = (\mathcal{H}^A \otimes \mathcal{H}^B) \oplus \mathcal{K}$.

(a) $\mathcal{H}^B$ is called a **noiseless subsystem** for Φ if for any $A \in B(\mathcal{H}^A)$ and $B \in B(\mathcal{H}^B)$, there is $A_E \in B(\mathcal{H}^A)$ such that

$$\Phi\,(A \otimes B) = A_E \otimes B. \tag{75.5}$$

(b) $\mathcal{H}^B$ is called a **correctable subsystem** for Φ if there is a quantum channel Ψ on $B(\mathcal{H})$ such that for any $A \in B(\mathcal{H}^A)$ and $B \in B(\mathcal{H}^B)$, there is $A_E \in B(\mathcal{H}^A)$ such that

$$(\Psi \circ \Phi)(A \otimes B) = A_E \otimes B. \tag{75.6}$$

Suppose $\mathcal{H} = \mathcal{H}^A \otimes \mathcal{H}^B$. Then we can identify $B(\mathcal{H})$ with $B(\mathcal{H}^A) \otimes B(\mathcal{H}^B)$. The **partial trace** tr_A is a linear map from $B(\mathcal{H})$ to $B(\mathcal{H}^B)$ defined by $\operatorname{tr}_A(A \otimes B) = \operatorname{tr}(A)B$ for $A \in B(\mathcal{H}^A)$ and $B \in B(\mathcal{H}^B)$. The partial trace $\operatorname{tr}_B : B(\mathcal{H}) \to B(\mathcal{H}^A)$ can be defined similarly.

Facts:

1. Let Φ be a quantum channel on $\mathcal{H}$ and $\mathcal{H} = \mathcal{H}_A \otimes \mathcal{H}_B \oplus \mathcal{K}$ as given previously. If $\dim \mathcal{H}^A = 1$, the noiseless subsystem $\mathcal{H}^B$ will be reduced to a decoherence free subspace. A noiseless subsystem is a correctable subsystem with identity map as the recovery channel. Also a correctable subsystem will reduce to a QECC if $\mathcal{H}^A$ has dimension 1. So the definition of correctable subsystem can be regarded as a unified formalism for all the techniques mentioned in the previous sections.
2. Let $P_V = U \begin{bmatrix} I_k & 0 \\ 0 & 0 \end{bmatrix} U^*$ for some unitary $U \in \mathbb{C}^{n\times n}$. The condition (75.4) can be restated as
$$\Phi\left(U \begin{bmatrix} \tilde{A} & 0 \\ 0 & 0 \end{bmatrix} U^*\right) = U \begin{bmatrix} \tilde{A} & 0 \\ 0 & 0 \end{bmatrix} U^* \quad \text{for all} \quad \tilde{A} \in \mathbb{C}^{k\times k}.$$
3. Condition (75.5) holds if and only if for every $B \in B(\mathcal{H}^B)$, there exists $A_E \in B(\mathcal{H}^A)$ such that
$$\Phi(I_A \otimes B) = A_E \otimes B.$$
4. Condition (75.5) holds if and only if for every $A \in B(\mathcal{H}^A)$ and $B \in B(\mathcal{H}^B)$,
$$\mathrm{tr}_A\left((P_{AB} \circ \Phi)(A \otimes B)\right) = B,$$
where P_{AB} is the orthogonal projection of $\mathcal{H}$ onto $\mathcal{H}^A \otimes \mathcal{H}^B$ and tr_A is the partial trace over the first subsystem $\mathcal{H}_A$.
5. Suppose $\dim \mathcal{H}^A = p$ and $\dim \mathcal{H}^B = k$ and identify $\mathcal{H}$ with $\mathbb{C}^n$. Then condition (75.5) holds if and only if there is a unitary matrix $U \in \mathbb{C}^{n\times n}$ so that for any $A \in \mathbb{C}^{p\times p}$ and $B \in \mathbb{C}^{k\times k}$, there exists $A_E \in \mathbb{C}^{p\times p}$ such that
$$\Phi\left(U \begin{bmatrix} A \otimes B & 0 \\ 0 & 0 \end{bmatrix} U^*\right) = U \begin{bmatrix} A_E \otimes B & 0 \\ 0 & 0 \end{bmatrix} U^*.$$
6. Suppose Φ is a quantum channel given by Eq. (75.1). Then the algebra $\mathcal{A}$ generated by $\{F_j,\ F_j^* : 1 \le j \le r\}$ admits the unique decomposition up to unitary similarity as
$$\bigoplus_j (\mathbb{C}^{n_j\times n_j} \otimes I_{s_j}) \qquad \text{with} \qquad \sum_j n_j s_j = n.$$
In other words, there is a unitary matrix $Q \in \mathbb{C}^{n\times n}$ such that for every error operator F_i in Eq. (75.1),
$$Q^* F_i Q = \bigoplus_j (F_{i,j} \otimes I_{s_j}) \qquad \text{with} \qquad F_{i,j} \in \mathbb{C}^{n_j\times n_j}.$$
Then for every index j, if we regard
$$\mathbb{C}^n = (\mathbb{C}^{n_j} \otimes \mathbb{C}^{s_j}) \oplus \mathbb{C}^q, \quad q = n - n_j s_j,$$
and if one applies the channel Φ to a quantum state $(A \otimes B) \oplus 0_q$ according to this decomposition, then
$$\Phi((A \otimes B) \oplus 0_q) = (A_E \otimes B) \oplus 0_q \quad \text{with} \quad A_E = \sum_i F_{i,j} A F_{i,j}^*$$
because of the special form of the error operators in this decomposition. Thus, the state $B \in \mathbb{C}^{s_j\times s_j}$ encoded as above will not be affected by the errors (noise) and can be

easily recovered. This gives rise to a noiseless subsystem. The situation is particularly pleasant if $n_j = 1$, i.e., we use the one-dimensional irreducible representation of $\mathcal{A}$, so that

$$\Phi(B \oplus 0_q) = B \oplus 0_q.$$

7. [KLP06] Condition (75.6) is equivalent to

$$\mathrm{tr}_A\left((P_{AB} \circ \Psi \circ \Phi)(A \otimes B)\right) = B \quad \text{for all} \quad A \in B(\mathcal{H}^A) \text{ and } B \in B(\mathcal{H}^B),$$

where P_{AB} is the orthogonal projection of $\mathcal{H}$ onto $\mathcal{H}^A \otimes \mathcal{H}^B$.

8. [KLP06] Let Φ be a quantum channel as given in Eq. (75.1). Then we have
   (a) Φ has a quantum error-correction code of dimension k if and only if there exist a unitary U and scalars λ_{ij} such that

   $$U^* F_i^* F_j U = \begin{bmatrix} \lambda_{ij} I_k & * \\ * & * \end{bmatrix} \quad \text{for all} \quad 1 \leq i, j \leq r.$$

   Here the entries at the positions denoted by $*$ are not restricted.

   (b) Φ has a decoherence free subspace of dimension k if and only if there exist a unitary U and scalars λ_j such that

   $$U^* F_j U = \begin{bmatrix} \lambda_j I_k & * \\ 0 & * \end{bmatrix} \quad \text{for all} \quad 1 \leq j \leq r.$$

   (c) Φ has a noiseless subsystem of dimension k if and only if there exist a unitary U and matrices $\Lambda_j \in \mathbb{C}^{p \times p}$ such that

   $$U^* F_j U = \begin{bmatrix} \Lambda_j \otimes I_k & * \\ 0 & * \end{bmatrix} \quad \text{for all} \quad 1 \leq j \leq r.$$

   (d) Φ has a correctable subsystem of dimension k if and only if there exist a unitary U and matrices $\Lambda_{i,j} \in \mathbb{C}^{p \times p}$ such that

   $$U^* F_i^* F_j U = \begin{bmatrix} \Lambda_{i,j} \otimes I_k & * \\ * & * \end{bmatrix} \quad \text{for all} \quad 1 \leq i, j \leq r.$$

Examples:

1. Consider the quantum channel $\Phi : \mathbb{C}^{4 \times 4} \to \mathbb{C}^{4 \times 4}$ with error operators

$$F_1 = \begin{bmatrix} \sqrt{1-2\alpha} & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & \sqrt{1-2\alpha} \end{bmatrix} \quad \text{and} \quad F_2 = \begin{bmatrix} \sqrt{\alpha} & 0 & 0 & 0 \\ 0 & 0 & 0 & \sqrt{\alpha} \\ \sqrt{\alpha} & 0 & 0 & 0 \\ 0 & 0 & 0 & \sqrt{\alpha} \end{bmatrix}$$

for some $0 \leq \alpha \leq 1$. Let $U = E_{11} + E_{24} + E_{33} + E_{42}$, where E_{ij} is the matrix with a 1 in the (i, j) position and zeros everywhere else. Then

$$U^* F_1 U = \begin{bmatrix} \sqrt{1-2\alpha} & 0 \\ 0 & 1 \end{bmatrix} \otimes I_2 \quad \text{and} \quad U^* F_2 U = \begin{bmatrix} \sqrt{\alpha} & 0 \\ \sqrt{\alpha} & 0 \end{bmatrix} \otimes I_2.$$

So for any $B \in \mathbb{C}^{2 \times 2}$,

$$\Phi\left(U(I_2 \otimes B)U^*\right) = U(A_E \otimes B)U^* \quad \text{where} \quad A_E = \begin{bmatrix} 1-\alpha & \alpha \\ \alpha & 1+\alpha \end{bmatrix}.$$

It follows that $\mathcal{H}^B$ is a noiseless subsystem if one decomposes $\mathcal{H}$ to $\mathcal{H}^A \otimes \mathcal{H}^B$, $\dim \mathcal{H}^A = \dim \mathcal{H}^B = 2$, with respect to the basis $\{|00\rangle, |11\rangle, |10\rangle, |01\rangle\}$.

2. Consider a quantum channel $\Phi : \mathbb{C}^{4\times 4} \to \mathbb{C}^{4\times 4}$ by $\Phi(A) = \sum_{j=1}^{2} F_j A F_j^*$, where

$$F_1 = \frac{1}{\sqrt{2}} \left(|00\rangle\langle 00| + |11\rangle\langle 10| + |00\rangle\langle 01| + |11\rangle\langle 11| \right),$$
$$F_2 = \frac{1}{\sqrt{2}} \left(|01\rangle\langle 00| + |10\rangle\langle 10| - |01\rangle\langle 01| - |10\rangle\langle 11| \right).$$

Let $U = E_{11} + E_{23} + E_{32} + E_{44}$. Then

$$U^\dagger F_1^\dagger F_1 U = \frac{1}{2}\begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix} \otimes I_2, \qquad U^\dagger F_2^\dagger F_1 U = U^\dagger F_1^\dagger F_2 U = 0_2 \otimes I_2, \text{ and}$$

$$U^\dagger F_2^\dagger F_2 U = \frac{1}{2}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix} \otimes I_2.$$

Define the recovery channel $\Psi : \mathbb{C}^{4\times 4} \to \mathbb{C}^{4\times 4}$ by $\Psi(B) = \sum_{j=1}^{4} R_j B R_j^*$ with

$$R_1 = \frac{1}{\sqrt{2}} \left(|00\rangle\langle 00| + |10\rangle\langle 11| \right), \quad R_2 = \frac{1}{\sqrt{2}} \left(|01\rangle\langle 00| + |11\rangle\langle 11| \right),$$
$$R_3 = \frac{1}{\sqrt{2}} \left(|00\rangle\langle 01| + |10\rangle\langle 10| \right), \quad R_4 = \frac{1}{\sqrt{2}} \left(|01\rangle\langle 01| + |11\rangle\langle 10| \right).$$

Direct computation shows that for any $B \in \mathbb{C}^{2\times 2}$,

$$(\Psi \circ \Phi)\big(U(I_2 \otimes B)U^*\big) = U(I_2 \otimes B)U^*.$$

It follows that $\mathcal{H}^B$ is a correctable subsystem when $\mathcal{H}$ is decomposed to $\mathcal{H}^A \otimes \mathcal{H}^B$ with respect to the basis $\{|00\rangle, |10\rangle, |01\rangle, |11\rangle\}$ and $\dim \mathcal{H}^A = \dim \mathcal{H}^B = 2$.

75.6 Quantum Error Correction without Syndrome Measurement

It was shown in [LNP12] that a recovery process can be done by unitary operations followed by a partial trace operation when the dimension k of the quantum error-correction code divides n, which is often the case in the context of quantum error correction with n and k being powers of 2.

Facts:

1. Let $\Phi : \mathbb{C}^{n\times n} \to \mathbb{C}^{n\times n}$ be a quantum channel as given in Eq. (75.1). Suppose the Knill-Laflamme condition in Eq. (75.3) holds for a k-dimensional orthogonal projection $P = WW^*$ with $W^*W = I_k$ and n being divisible by k. Then there is a unitary $R \in \mathbb{C}^{n\times n}$ and a density matrix $D \in \mathbb{C}^{(n/k)\times(n/k)}$ such that for any density matrix $\tilde{A} \in \mathbb{C}^{k\times k}$ and $A = W\tilde{A}W^* \in \mathbb{C}^{n\times n}$, $PAP = A$ and

$$R^*\, \Phi(A)\, R = D \otimes \tilde{A}. \tag{75.7}$$

So a recovery channel can be constructed as the map $\Psi : \mathbb{C}^{n\times n} \to \mathbb{C}^{n\times n}$ defined by

$$\Psi(B) = W(\,\mathrm{tr}_1\,(R^* B R)\,)W^*,$$

where tr_1 stands for the partial trace over the first subsystem (encoding ancilla Hilbert space) so that $\mathrm{tr}_1(D \otimes \tilde{A}) = (\mathrm{tr}\, D)\tilde{A}$ in Eq. (75.7).

Examples:

1. Consider the three qubit bit-flip channel $\Phi : \mathbb{C}^{8\times 8} \to \mathbb{C}^{8\times 8}$ with error operators $\sqrt{p_0}X_0$, $\sqrt{p_1}X_2$, $\sqrt{p_2}X_2$, $\sqrt{p_3}X_3$, where X_j are the operators defined in Example 75.3.1 and $\sum_{j=0}^{3} p_j = 1$. Then $V = \operatorname{span}\{|000\rangle, |111\rangle\}$ is a QECC with $P_V = E_{11}+E_{88}$. The recovery channel given by Eq. (75.2) is not easy to implement. Now one can write $P_V = WW^*$ with $W^*W = I_2$, where

$$W = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}^* .$$

A one-qubit state $|\psi_0\rangle = \alpha|0\rangle + \beta|1\rangle$ is encoded with two encoding ancilla qubits as $|\psi\rangle = \alpha|000\rangle + \beta|111\rangle$. Let

$$\tilde{A} = |\psi_0\rangle\langle\psi_0| = \begin{bmatrix} |\alpha|^2 & \alpha\overline{\beta} \\ \overline{\alpha}\beta & |\beta|^2 \end{bmatrix}.$$

The encoded state is then

$$A = W\tilde{A}W^* = \begin{bmatrix} |\alpha|^2 & 0 & 0 & 0 & 0 & 0 & 0 & \alpha\overline{\beta} \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \vdots & & \vdots & & & \vdots & & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ \overline{\alpha}\beta & 0 & 0 & 0 & 0 & 0 & 0 & |\beta|^2 \end{bmatrix}.$$

Define $D = \operatorname{diag}(p_0, p_1, p_2, p_3)$ and

$$R = E_{11} + E_{27} + E_{35} + E_{44} + E_{53} + E_{66} + E_{78} + E_{82}.$$

Then

$$R^*\Phi(A)R = D \otimes \tilde{A}.$$

Now the decoded state $\tilde{A}$ appears in the output with no syndrome measurements or explicit projection. It should be pointed out that the unitary operation R is independent of the choice of nonnegative numbers p_j.

Information retrieval is the process of searching within a document collection for information most relevant to a user's query. However, the type of document collection significantly affects the methods and algorithms used to process queries. In this chapter, we distinguish between two types of document collections: traditional and Web collections. Traditional information retrieval is search within small, controlled, nonlinked collections (e.g., a collection of medical or legal documents), whereas Web information retrieval is search within the world's largest and linked document collection. In spite of the proliferation of the Web, more traditional nonlinked collections still exist, and there is still a place for the older methods of information retrieval.

76.1 The Traditional Vector Space Method

Today most search systems that deal with traditional document collections use some form of the vector space method [SB83] developed by Gerard Salton in the early 1960s. Salton's method transforms textual data into numeric vectors and matrices and employs matrix analysis techniques to discover key features and connections in the document collection.

Definitions:

For a given collection of documents and for a dictionary of m terms, document i is represented by an $m \times 1$ **document vector** $\mathbf{d}_i$ whose jth element is the number of times term j appears in document i.

The **term-by-document matrix** is the $m \times n$ matrix

$$A = [\mathbf{d}_1\, \mathbf{d}_2\, \cdots\, \mathbf{d}_n]$$

whose columns are the document vectors.

Recall is a measure of performance that is defined to be

$$0 \leq \text{Recall} := \frac{\#\text{ relevant docs retrieved}}{\#\text{ relevant docs in collection}} \leq 1.$$

Precision is another measure of performance, defined to be

$$0 \leq \text{Precision} := \frac{\#\text{ relevant docs retrieved}}{\#\text{ docs retrieved}} \leq 1.$$

Query processing is the act of retrieving documents from the collection that are most related to a user's query, and the **query vector** $\mathbf{q}_{m\times 1}$ is the binary vector defined by

$$q_i = \begin{cases} 1 & \text{if term } i \text{ is present in the user's query,} \\ 0 & \text{otherwise.} \end{cases}$$

The **relevance** of document i to a query $\mathbf{q}$ is defined to be

$$\delta_i = cos\,\theta_i = \mathbf{q}^T\mathbf{d}_i/\|\mathbf{q}\|_2\|\mathbf{d}_i\|_2.$$

For a selected tolerance τ, the **retrieved documents** that are returned to the user are the documents for which $\delta_i > \tau$.

Facts:

1. The term-by-document matrix A is sparse and nonnegative, but otherwise unstructured.
2. [BB05] In practice, weighting schemes other than raw frequency counts are used to construct the term-by-document matrix because weighted frequencies can improve performance.
3. [BB05] Query weighting may also be implemented in practice.
4. The tolerance τ is usually tuned to the specific nature of the underlying document collection.
5. Tuning can be accomplished with the technique of relevance feedback, which uses a revised query vector such as $\tilde{\mathbf{q}} = \delta_1\mathbf{d}_1 + \delta_3\mathbf{d}_3 + \delta_7\mathbf{d}_7$, where $\mathbf{d}_1$, $\mathbf{d}_3$, and $\mathbf{d}_7$ are the documents the user judges most relevant to a given query $\mathbf{q}$.
6. When the columns of A and $\mathbf{q}$ are normalized, as they usually are, the vector $\boldsymbol{\delta}^T = \mathbf{q}^T A$ provides the complete picture of how well each document in the collection matches the query.
7. The vector space model is efficient because A is usually very sparse, and $\mathbf{q}^T A$ can be executed in parallel, if necessary.
8. [BB05] Because of linguistic issues such as polysomes and synonyms, the vector space model provides only decent performance on query processing tasks.
9. The underlying basis for the vector space model is the standard basis $\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_m$, and the orthogonality of this basis can impose an unrealistic independence among terms.
10. The vector space model is a good starting place, but variations have been developed that provide better performance.

Examples:

1. Consider a collection of seven documents and nine terms (taken from [BB05]). Terms not in the system's index are ignored. Suppose further that only the titles of each document are used for indexing. The indexed terms and titles of documents are shown next.

Terms	Documents
T1: Bab(y,ies,y's)	D1: *Infant* & *Toddler* First Aid
T2: Child(ren's)	D2: *Babies* and *Children's* Room (For Your *Home*)
T3: Guide	D3: *Child Safety* at *Home*
T4: Health	D4: Your *Baby's Health* and *Safety*: From *Infant* to *Toddler*
T5: Home	D5: *Baby Proofing* Basics
T6: Infant	D6: Your *Guide* to Easy Rust *Proofing*
T7: Proofing	D7: Beanie *Babies* Collector's *Guide*
T8: Safety	
T9: Toddler	

The indexed terms are italicized in the titles. Also, the stems [BB05] of the terms for baby (and its variants) and child (and its variants) are used to save storage and improve performance. The term-by-document matrix for this document collection is

$$A = \begin{bmatrix} 0 & 1 & 0 & 1 & 1 & 0 & 1 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 & 0 & 0 \end{bmatrix}.$$

For a query on *baby health*, the query vector is

$$\mathbf{q} = \begin{bmatrix}1\ 0\ 0\ 1\ 0\ 0\ 0\ 0\ 0\end{bmatrix}^T.$$

To process the user's query, the cosines

$$\delta_i = cos\,\theta_i = \frac{\mathbf{q}^T\mathbf{d}_i}{\|\mathbf{q}\|_2\|\mathbf{d}_i\|_2}$$

are computed. The documents corresponding to the largest elements of $\boldsymbol{\delta}$ are most relevant to the user's query. For our example,

$$\boldsymbol{\delta} \approx \begin{bmatrix}0\ 0.40824\ 0\ 0.63245\ 0.5\ 0\ 0.5\end{bmatrix},$$

so document vector 4 is scored most relevant to the query on *baby health.* To calculate the recall and precision scores, one needs to be working with a small, well-studied document collection. In this example, documents $\mathbf{d}_4$, $\mathbf{d}_1$, and $\mathbf{d}_3$ are the three documents in the collection relevant to baby health. Consequently, with $\tau = .1$, the recall score is 1/3 and the precision is 1/4.

76.2 Latent Semantic Indexing

In the 1990s, an improved information retrieval system replaced the vector space model. This system is called Latent Semantic Indexing (LSI) [Dum91] and was the product of Susan Dumais, then at Bell Labs. LSI simply creates a low rank approximation A_k to the term-by-document matrix A from the vector space model.

Facts:

1. [Mey00] If the term-by-document matrix $A_{m\times n}$ has the singular value decomposition $A = U\Sigma\ V^T = \sum_{i=1}^{r} \sigma_i \mathbf{u}_i \mathbf{v}_i^T$, $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_r > 0$, then A_k is created by truncating this expansion after k terms, where k is a user tunable parameter.
2. The recall and precision measures are generally used in conjunction with each other to evaluate performance.
3. A is replaced by $A_k = \sum_{i=1}^{k} \sigma_i \mathbf{u}_i \mathbf{v}_i^T$ in the query process so that if $\mathbf{q}$ and the columns of A_k have been normalized, then the angle vector is computed as $\boldsymbol{\delta}^T = \mathbf{q}^T A_k$.
4. The truncated SVD approximation to A is optimal in the sense that of all rank-k matrices, the truncated SVD A_k is the closest to A, and

$$\|A - A_k\|_F = \min_{rank(B)\leq k} \|A - B\|_F = \sqrt{\sigma_{k+1}^2 + \cdots + \sigma_r^2}.$$

5. This rank-k approximation reduces the so-called linguistic noise present in the term-by-document matrix and, thus, improves information retrieval performance.
6. [Dum91], [BB05], [BR99], [Ber01], [BDJ99] LSI is known to outperform the vector space model in terms of precision and recall.
7. [BR99], [Ber01], [BB05], [BF96], [BDJ99], [BO98], [Blo99], [BR01], [Dum91], [HB00], [JL00], [JB00], [LB97], [WB98], [ZBR01], [ZMS98] LSI and the truncated singular value decomposition dominated text mining research in the 1990s.
8. A serious drawback to LSI is that while it might appear at first glance that A_k should save storage over the original matrix A, this is often not the case, even when $k << r$. This is because A is generally very sparse, but the singular vectors $\mathbf{u}_i$ and $\mathbf{v}_i^T$ are almost always completely dense. In many cases, A_k requires more (sometimes much more) storage than A itself requires.
9. A significant problem with LSI is the fact that while A is a nonnegative matrix, the singular vectors are mixed in sign. This loss of important structure means that the truncated singular value decomposition provides no textual or semantic interpretation. Consider a particular document vector, say, column 1 of A. The truncated singular value decomposition represents document 1 as

$$A_1 = \begin{bmatrix} \vdots \\ \mathbf{u}_1 \\ \vdots \end{bmatrix} \sigma_1 v_{11} + \begin{bmatrix} \vdots \\ \mathbf{u}_2 \\ \vdots \end{bmatrix} \sigma_2 v_{12} + \cdots + \begin{bmatrix} \vdots \\ \mathbf{u}_k \\ \vdots \end{bmatrix} \sigma_k v_{1k},$$

   so document 1 is a linear combination of the basis vectors $\mathbf{u}_i$ with the scalar $\sigma_i v_{1i}$ being a weight that represents the contribution of basis vector i in document 1. What we would really like to do is say that basis vector i is mostly concerned with some subset of the terms, but any such textual or semantic interpretation is difficult (or impossible) when SVD components are involved. Moreover, if there were textual or semantic interpretations, the orthogonality of the singular vectors would ensure that there is no overlap of terms in the topics in the basis vectors, which is highly unrealistic.

10. [Ber01], [ZMS98] It is usually a difficult problem to determine the most appropriate value of k for a given dataset because k must be large enough so that A_k can capture the essence of the document collection, but small enough to address storage and computational issues. Various heuristics have been developed to deal with this issue.

Examples:

1. Consider again the 9×7 term-by-document matrix used in Section 76.1. The rank-4 approximation to this matrix is

$$A_4 = \begin{bmatrix} 0.020 & 1.048 & -0.034 & 0.996 & 0.975 & 0.027 & 0.975 \\ -0.154 & 0.883 & 1.067 & 0.078 & 0.027 & -0.033 & 0.027 \\ -0.012 & -0.019 & 0.013 & 0.004 & 0.509 & 0.990 & 0.509 \\ 0.395 & 0.058 & 0.020 & 0.756 & 0.091 & -0.087 & 0.091 \\ -0.154 & 0.883 & 1.067 & 0.078 & 0.027 & -0.033 & 0.027 \\ 0.723 & -0.144 & 0.068 & 1.152 & 0.004 & -0.012 & 0.004 \\ -0.012 & -0.019 & 0.013 & 0.004 & 0.509 & 0.990 & 0.509 \\ 0.443 & 0.334 & 0.810 & 0.776 & -0.074 & 0.091 & -0.074 \\ 0.723 & -0.144 & 0.068 & 1.152 & 0.004 & -0.012 & 0.004 \end{bmatrix}.$$

Notice that while A is sparse and nonnegative, A_4 is dense and mixed in sign. Of course, as k increases, A_k looks more and more like A. For a query on *baby health*, the angle vector is

$$\boldsymbol{\delta} \approx \begin{bmatrix} .244 & .466 & -.006 & .564 & .619 & -.030 & .619 \end{bmatrix}^T.$$

Thus, the information retrieval system returns documents $\mathbf{d}_5$, $\mathbf{d}_7$, $\mathbf{d}_4$, $\mathbf{d}_2$, $\mathbf{d}_1$, in order from most to least relevant. As a result, the recall improves to 2/3, while the precision is 2/5. Adding another singular triplet and using the approximation matrix A_5 does not change the recall or precision measures, but does give a slightly different angle vector

$$\boldsymbol{\delta} \approx \begin{bmatrix} .244 & .466 & -.006 & .564 & .535 & -.030 & .535 \end{bmatrix}^T,$$

which is better than the A_4 angle vector because the most relevant document, $\mathbf{d}_4$, *Your Baby's Health and Safety: From Infant to Toddler*, gets the highest score.

76.3 Nonnegative Matrix Factorizations

The lack of semantic interpretation due to the mixed signs in the singular vectors is a major obstacle in using LSI. To circumvent this problem, alternative low rank approximations that maintain the nonnegative structure of the original term-by-document matrix have been proposed [LS99], [LS01], [PT94], [PT97].

Facts:

1. If $A_{m\times n} \geq 0$ has rank r, then for a given $k < r$ the goal of a nonnegative matrix factorization (NMF) is to find the nearest rank-k approximation WH to A such that $W_{m\times k} \geq 0$ and $H_{k\times n} \geq 0$. Once determined, an NMF simply replaces the truncated singular value decomposition in any text mining task such as clustering documents, classifying documents, or processing queries on documents.

2. An NMF can be formulated as a constrained nonlinear least squares problem by first specifying k and then determining

$$\min \|A - WH\|_F^2 \quad \text{subject to} \quad W_{m\times k} \geq 0, \quad H_{k\times n} \geq 0.$$

   The rank of the approximation (i.e., k) becomes the number of topics or clusters in a text mining application.
3. [LS99] The Lee and Seung algorithm to compute an NMF using MATLAB is as follows.

Algorithm 1: Lee–Seung NMF

```
$W = \text{abs}(\text{randn}(m,k))$                  % initialize with random dense matrix
$H = \text{abs}(\text{randn}(k,n))$                  % initialize with random dense matrix
for $i = 1 : \text{maxiter}$
    $H = H.*(W^TA)./(W^TWH + 10^{-9})$    % $10^{-9}$ avoids division by 0
    $W = W.*(AH^T)./(WHH^T + 10^{-9})$
end
```

4. The objective function $\|A - WH\|_F^2$ in the Lee and Seung algorithm tends to tail off within 50 to 100 iterations. Faster algorithms exist, but the Lee and Seung algorithm is guaranteed to converge to a local minimum in a finite number of steps.
5. [Hoy02], [Hoy04], [SBP04] Other NMF algorithms contain a tunable sparsity parameter that produces any desired level of sparseness in W and H. The storage savings of the NMF over the truncated SVD are substantial.
6. Because $A_j \approx \sum_{i=1}^{k} W_i h_{ij}$, and because W and H are nonnegative, each column W_i can be viewed as a topic vector—if $w_{ij_1}, w_{ij_2}, \ldots, w_{ij_p}$ are the largest entries in W_i, then terms $j_1, j_2, \ldots, j_p$ dictate the topics that W_i represents. The entries h_{ij} measure the strength to which topic i appears in basis document j, and k is the number of topic vectors that one expects to see in a given set of documents.
7. The NMF has some disadvantages. Unlike the SVD, uniqueness and robust computations are missing in the NMF. There is no unique global minimum for the NMF (the defining constrained least squares problem is not convex in W and H), so algorithms can only guarantee convergence to a local minimum, and many do not even guarantee that.
8. Not only will different NMF algorithms produce different NMF factors, the same NMF algorithm, run with slightly different parameters, can produce very different NMF factors. For example, the results can be highly dependent on the initial values.

Examples:

1. When the term-by-document matrix of the MEDLINE dataset [Med03] is approximated with an NMF as described above with $k = 10$, the charts in Figure 76.1 show the highest weighted terms from four representative columns of W. For example, this makes it clear that W_1 represents heart-related topics, while W_2 concerns blood issues, etc.

   When document 5 (column A_5) from MEDLINE is expressed as an approximate linear combination of $W_1, W_2, \ldots, W_{10}$ in order of the size of the entries of H_5, which are

$$h_{95} = .1646 > h_{65} = .0103 > h_{75} = .0045 > \cdots,$$

   we have that

$$A_5 \approx .1646\, W_9 + .0103\, W_6 + .0045\, W_7 + \cdots$$

$$= .1646 \begin{bmatrix} \text{fatty} \\ \text{glucose} \\ \text{acids} \\ \text{ffa} \\ \text{insulin} \\ \vdots \end{bmatrix} + .0103 \begin{bmatrix} \text{kidney} \\ \text{marrow} \\ \text{dna} \\ \text{cells} \\ \text{nephr.} \\ \vdots \end{bmatrix} + .0045 \begin{bmatrix} \text{hormone} \\ \text{growth} \\ \text{hgh} \\ \text{pituitary} \\ \text{mg} \\ \vdots \end{bmatrix} + \cdots .$$

Therefore, document 5 is largely about terms contained in topic vector W_9 followed by topic vectors W_6 and W_7.

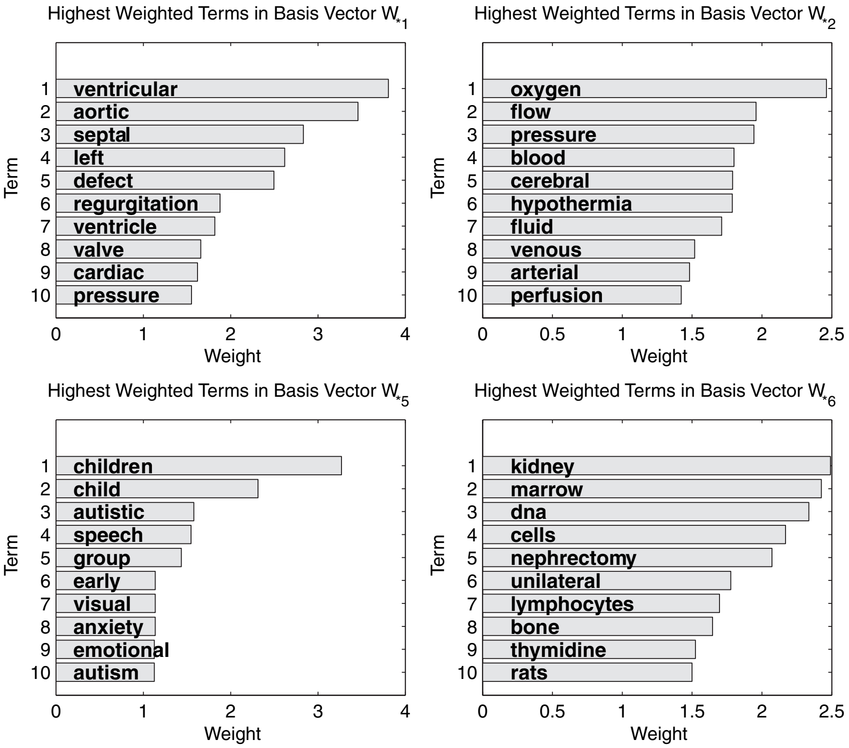

FIGURE 76.1 MEDLINE charts.

2. Consider the same 9×7 term-by-document matrix A from the Example 76.1.1. A rank-4 approximation $A_4 = W_{9\times4}H_{4\times7}$ that is produced by the Lee and Seung algorithm is

$$A_4 = \begin{bmatrix} 0.027 & 0.888 & 0.196 & 1.081 & 0.881 & 0.233 & 0.881 \\ 0 & 0.852 & 1.017 & 0.173 & 0.058 & 0.031 & 0.058 \\ 0.050 & 0.084 & 0.054 & 0.102 & 0.496 & 0.899 & 0.496 \\ 0.360 & 0.172 & 0.073 & 0.729 & 0.179 & 0.029 & 0.179 \\ 0 & 0.852 & 1.017 & 0.173 & 0.058 & 0.031 & 0.058 \\ 0.760 & 0.032 & 0.155 & 1.074 & 0.033 & 0.061 & 0.033 \\ 0.050 & 0.084 & 0.054 & 0.102 & 0.496 & 0.899 & 0.496 \\ 0.445 & 0.481 & 0.647 & 0.718 & 0.047 & 0.053 & 0.047 \\ 0.760 & 0.032 & 0.155 & 1.074 & 0.033 & 0.061 & 0.033 \end{bmatrix},$$

where

$$W_4 = \begin{bmatrix} 0.202 & 0.017 & 0.160 & 1.357 \\ 0 & 0 & 0.907 & 0.104 \\ 0.805 & 0 & 0 & 0.008 \\ 0 & 0.415 & 0 & 0.321 \\ 0 & 0 & 0.907 & 0.104 \\ 0 & 0.875 & 0 & 0.060 \\ 0.805 & 0 & 0 & 0.008 \\ 0 & 0.513 & 0.500 & 0.085 \\ 0 & 0.876 & 0 & 0.060 \end{bmatrix},$$

$$H_4 = \begin{bmatrix} 0.062 & 0.010 & 0.067 & 0.119 & 0.610 & 1.117 & 0.610 \\ 0.868 & 0 & 0.177 & 1.175 & 0 & 0.070 & 0 \\ 0 & 0.878 & 1.121 & 0.105 & 0 & 0.034 & 0 \\ 0 & 0.537 & 0 & 0.752 & 0.559 & 0 & 0.559 \end{bmatrix}.$$

Notice that both A and A_4 are nonnegative, and the sparsity of W and H makes the storage savings apparent. The error in this NMF approximation as measured by $\|A - WH\|_F^2$ is 1.56, while the error in the best rank-4 approximation from the truncated SVD is 1.42. In other words, the NMF approximation is not far from the optimal SVD approximation — this is frequently the case in practice in spite of the fact that W and H can vary with the initial conditions. For a query on *baby health*, the angle vector is

$$\boldsymbol{\delta} \approx \left[.224 .472 .118 .597 .655 .143 .655\right]^T .$$

Thus, the information retrieval system that uses the nonnegative matrix factorization gives the same ranking as a system that uses the truncated singular value decomposition. However, the factors are sparse and nonnegative and can be interpreted.

76.4 Web Search

Only a few years ago, users of Web search engines were accustomed to waiting, for what would now seem to be an eternity, for search engines to return results to their queries. And when a search engine finally responded, the returned list was littered with links to information that was irrelevant, unimportant, or downright useless. Frustration was compounded by the fact that useless links invariably appeared at or near the top of the list while useful links were deeply buried. Users had to sift through links a long way down in the list to have a chance of finding something satisfying, and being less than satisfied was not uncommon.

The reason for this is that the Web's information is not structured like information in the organized databases and document collections on which generations of computer scientists had honed their techniques. The Web is unique in the sense that it is *self-organized.* That is, unlike traditional document collections that are accumulated, edited, and categorized by trained specialists, the Web has no standards, no reviewers, and no gatekeepers to police content, structure, and format. Information on the Web is volatile and heterogeneous — links and data are rapidly created, changed, and removed, and Web information exists in multiple formats, languages, and alphabets. And there is a multitude of different purposes for Web data, e.g., some Web pages are designed to inform while others try to sell, cheat, steal, or seduce. In addition, the Web's self-organization opens the door for spammers, the nefarious people who want to illicitly commandeer your attention to sell or advertise something that you probably do not want. Web spammers are continually devising diabolical schemes to trick search engines into listing their (or their client's) Web pages near the top of the list of search results. They had an easy time of it when Web search relied on traditional IR methods based on semantic principles. Spammers could create Web pages that contained things such as miniscule or hidden text fonts, hidden text with white fonts on a white background, and misleading metatag descriptions designed to influence semantic-based search engines. Finally, the enormous size of the Web, currently containing $O(10^9)$ pages, completely overwhelmed traditional IR techniques.

By 1997 it was clear that in nearly all respects the database and IR technology of the past was not well suited for Web search, so researchers set out to devise new approaches. Two big ideas emerged (almost simultaneously), and each capitalizes on the link structure of the Web to differentiate between relevant information and fluff. One approach, HITS (Hypertext Induced Topic Search), was introduced by Jon Kleinberg [Kle99], [LM06a], and the other, which changed everything, is Google's *PageRank*™ that was developed by Sergey Brin and Larry Page [BP98], [BPM99], [LM06a]. While variations of HITS and PageRank followed (e.g., Lempel's SALSA [LM00], [LM05], [LM06a]), the basic idea of PageRank became the driving force, so the focus is on this concept.

Definitions:

Early in the game, search companies such as Yahoo!® employed students to surf the Web and record key information about the pages they visited. This quickly overwhelmed human capability, so today all Web search engines use **Web Crawlers,** which is software that continuously scours the Web for information to return to a central repository.

Web pages found by the robots are temporarily stored in entirety in a **page repository.** Pages remain in the repository until they are sent to an indexing module, where their vital information is stripped to create a compressed version of the page. Popular pages that are repeatedly requested by users are stored here longer, perhaps indefinitely.

The **indexing module** extracts only key words, key phrases, or other vital descriptors, and it creates a compressed description of the page that can be "indexed." Depending on the popularity of a page, the uncompressed version is either deleted or returned to the page repository.

There are three general kinds of **indices** that contain compressed information for each Web page.

The **content index** contains information such as key words or phrases, titles, and anchor text, and this is stored in a compressed form using an **inverted file** structure, which is simply the electronic version of a book index, i.e., each morsel of information points to a list of pages containing it.

Information regarding the hyperlink structure of a page is stored in compressed form in the **structure index**. The crawler module sometimes accesses the structure index to find uncrawled pages.

Finally, there are **special-purpose indices** such as an image index and a pdf index. The crawler, page repository, indexing module, and indices, along with their corresponding data files, exist and operate independent of users and their queries.

The **query module** converts a user's natural language query into a language that the search engine can understand (usually numbers), and consults the various indices in order to answer the query. For example, the query module consults the content index and its inverted file to find which pages contain the query terms.

The **pertinent pages** are the pages that contain query terms. After pertinent pages have been identified, the query module passes control to the ranking module.

The **ranking module** takes the set of pertinent pages and ranks them according to some criterion, and this criterion is the heart of the search engine — it is the distinguishing characteristic that differentiates one search engine from another. The ranking criterion must somehow discern which Web pages best respond to a user's query, a daunting task because there might be millions of pertinent pages. Unless a search engine wants to play the part of a censor (which most do not), the user is given the opportunity of seeing a list of links to a large proportion of the pertinent pages, but with less useful links permuted downward.

PageRank is Google's patented ranking system, and some of the details surrounding PageRank are discussed below.

Facts:

1. Google assigns at least two scores to each Web page. The first is a popularity score and the second is a content score. Google blends these two scores to determine the final ranking of the results that are returned in response to a user's query.
2. [BP98] The rules used to give each pertinent page a content score are trade secrets, but they generally take into account things such as whether the query terms appear in the title or deep in the body of a Web page, the number of times query terms appear in a page, the proximity of multiple query words to one another, and the appearance of query terms in a page (e.g., headings in bold font score higher). The content of neighboring Web pages is also taken into account.
3. Google is known to employ over 100 such metrics in this regard, but the details are proprietary. While these metrics are important, they are secondary to the popularity score, which is the primary component of PageRank. The content score is used by Google only to temper the popularity score.

76.5 Google's PageRank

The popularity score is where the mathematics lies, so it is the focus of the remainder of this exposition. We will identify the term "PageRank" with just the mathematical component of Google's PageRank (the popularity score) with the understanding that PageRank may be tweaked by a content score to produce a final ranking.

Both PageRank and Google were conceived by Sergey Brin and Larry Page while they were computer science graduate students at Stanford University, and in 1998 they took a leave of absence to focus on their growing business. In a public presentation at the Seventh International World Wide Web conference (WWW98) in Brisbane, Australia, their paper "The PageRank Citation Ranking: Bringing Order to the Web" [BPM99] made small ripples in the information science community that quickly turned into waves.

The original idea was that a *page is important if it is pointed to by other important pages.* That is, the importance of your page (its PageRank) is determined by summing the PageRanks of all pages that point to yours. Brin and Page also reasoned that when an important page points to several places, its weight (PageRank) should be distributed proportionately.

In other words, if YAHOO! points to 99 pages in addition to yours, then you should only get credit for 1/100 of YAHOO!'s PageRank. This is the intuitive motivation behind Google's PageRank concept, but significant modifications are required to turn this basic idea into something that works in practice.

For readers who want to know more, the book *Google's PageRank and Beyond: The Science of Search Engine Rankings* [LM06a] contains over 250 pages devoted to link analysis algorithms, along with other ranking schemes such as HITS and SALSA as well as additional background material, examples, code, and chapters dealing with more advanced issues in Web search ranking.

Definitions:

The **hyperlink matrix** is the matrix $H_{n\times n}$ that represents the link structure of the Web, and its entries are given by

$$h_{ij} = \begin{cases} 1/|O_i| & \text{if there is a link from page } i \text{ to page } j, \\ 0 & \text{otherwise,} \end{cases}$$

where $|O_i|$ is the number of outlinks from page i.

Suppose that there are n Web pages, and let $r_i(0)$ denote the initial rank of the ith page. If the ranks are successively modified by setting

$$r_i(k+1) = \sum_{j\in I_i} \frac{r_j(k)}{|O_j|}, \quad k = 1, 2, 3, \ldots,$$

where $r_i(k)$ is the rank of page i at iteration k and I_i is the set of pages pointing (linking) to page i, then the rankings after the kth iteration are

$$\mathbf{r}^T(k) = (r_1(k),\, r_2(k),\, \ldots,\, r_n(k)) = \mathbf{r}^T(0)H^k.$$

The **conceptual PageRank** of the ith Web page is defined to be

$$r_i = \lim_{k\to\infty} r_i(k),$$

provided that the limit exists. However, this definition is strictly an intuitive concept because the natural structure of the Web generally prohibits these limits from existing.

A **dangling node** is a Web page that contain no out links. Dangling nodes produce zero rows in the hyperlink matrix H, so even if $\lim_{k\to\infty} H^k$ exists, the limiting vector $\mathbf{r}^T = \lim_{k\to\infty} \mathbf{r}^T(k)$ would be dependent on the initial vector $\mathbf{r}^T(0)$, which is not good.

The **stochastic hyperlink matrix** is produced by perturbing the hyperlink matrix to be stochastic. In particular,

$$S = H + \mathbf{a}\mathbf{1}^T/n, \tag{76.1}$$

where $\mathbf{a}$ is the column in which

$$a_i = \begin{cases} 1 & \text{if page } i \text{ is a dangling node,} \\ 0 & \text{otherwise.} \end{cases}$$

S is a stochastic matrix that is identical to H except that zero rows in H are replaced by $\mathbf{1}^T/n$ ($\mathbf{1}$ is a vector of 1s and $n = O(10^9)$, so entries in $\mathbf{1}^T/n$ are pretty small). The effect is to eliminate dangling nodes. Any probability vector $\mathbf{p}^T > 0$ can be used in place of the uniform vector.

The **Google matrix** is defined to be the stochastic matrix

$$G = \alpha S + (1-\alpha)E, \tag{76.2}$$

where $E = \mathbf{1}\mathbf{v}^T$ in which $\mathbf{v}^T > 0$ can be any probability vector. Google originally set $\alpha = .85$ and $\mathbf{v}^T = \mathbf{1}^T/n$. The choice of α is discussed later in Facts 12, 13, and 14.

The **personalization vector** is the vector $\mathbf{v}^T$ in $E = \mathbf{1}\mathbf{v}^T$ in Eq. (76.2). Manipulating $\mathbf{v}^T$ gives Google the flexibility to make adjustments to PageRanks as well as to personalize them (thus, the name "personalization vector") [HKJ03], [LM04].

The **PageRank vector** is the left Perron vector (i.e., stationary distribution) $\boldsymbol{\pi}^T$ of the Google matrix G. In particular, $\boldsymbol{\pi}^T(I - G) = 0$, where $\boldsymbol{\pi}^T > 0$ and $\|\boldsymbol{\pi}^T\|_1 = 1$. The components of this vector constitute Google's popularity score of each Web page.

Facts:

1. [Mey00, Chap. 8] The Google matrix G is a primitive stochastic matrix, so the spectral radius $\rho(G) = 1$ is a simple eigenvalue, and 1 is the only eigenvalue on the unit circle.

2. The iteration defined by $\boldsymbol{\pi}^T(k+1) = \boldsymbol{\pi}^T(k)G$ converges, independent of the starting vector, to a unique stationary probability distribution $\boldsymbol{\pi}^T$, which is the PageRank vector.
3. The irreducible aperiodic Markov chain defined by $\boldsymbol{\pi}^T(k+1) = \boldsymbol{\pi}^T(k)G$ is a constrained random walk on the Web graph. The random walker can be characterized as a Web surfer who, at each step, randomly chooses a link from his current page to click on except that
   (a) When a dangling node is encountered, the excursion is continued by jumping to another page selected at random (i.e., with probability $1/n$).
   (b) At each step, the random Web surfer has a chance (with probability $1-\alpha$) of becoming bored with following links from the current page, in which case the random Web surfer continues the excursion by jumping to page j with probability v_j.
4. The random walk defined by $\mathbf{r}^T(k+1) = \mathbf{r}^T(k)S$ will generally not converge because the Web's graph structure is not strongly connected, which results in a reducible chain with many isolated ergodic classes.
5. The power method has been Google's computational method of choice for computing the PageRank vector. If formed explicitly, G is completely dense, and the size of n would make each power iteration extremely costly — billions of flops for each step. But writing the power method as

$$\boldsymbol{\pi}^T(k+1) = \boldsymbol{\pi}^T(k)G = \alpha\boldsymbol{\pi}^T(k)H + (\alpha\boldsymbol{\pi}^T(k)\mathbf{a})\mathbf{1}^T/n + (1-\alpha)\mathbf{v}^T$$

   shows that only extremely sparse vector-matrix multiplications are required. Only the nonzero h_{ij}'s are needed, so G and S are neither formed nor stored.
6. When implemented as shown above, each power step requires only $nnz(H)$ flops, where $nnz(H)$ is the number of nonzeros in H, and, since the average number of nonzeros per column in H is significantly less than 10, we have $O(nnz(H)) \approx O(n)$. Furthermore, the inherent parallism is easily exploited, and the current iterate is the only vector stored at each step.
7. Because the Web has many disconnected components, the hyperlink matrix is highly reducible, and compensating for the dangling nodes to construct the stochastic matrix S does not significantly affect this.
8. [Mey00, pp. 695–696] Since S is also reducible, S can be symmetrically permuted to have the form

$$S \sim \left[\begin{array}{cccc|cccc} S_{11} & S_{12} & \cdots & S_{1r} & S_{1,r+1} & S_{1,r+2} & \cdots & S_{1m} \\ 0 & S_{22} & \cdots & S_{2r} & S_{2,r+1} & S_{2,r+2} & \cdots & S_{2m} \\ \vdots & & \ddots & \vdots & \vdots & \vdots & \cdots & \vdots \\ 0 & 0 & \cdots & S_{rr} & S_{r,r+1} & S_{r,r+2} & \cdots & S_{rm} \\ \hline 0 & 0 & \cdots & 0 & S_{r+1,r+1} & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 & 0 & S_{r+2,r+2} & \cdots & 0 \\ \vdots & \vdots & \cdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 & 0 & 0 & \cdots & S_{mm} \end{array}\right],$$

   where the following are true.
   (a) For each $1 \le i \le r$, S_{ii} is either irreducible or $[0]_{1\times 1}$.
   (b) For each $1 \le i \le r$, there exists some $j > i$ such that $S_{ij} \neq 0$.

   (c) $\rho(S_{ii}) < 1$ for each $1 \leq i \leq r$.
   (d) $S_{r+1,r+1}$, $S_{r+2,r+2}, \cdots, S_{m,m}$ are each stochastic and irreducible.
   (e) 1 is an eigenvalue for S that is repeated exactly $m - r$ times.

9. The natural structure of the Web forces the algebraic multiplicity of the eigenvalue 1 to be large.
10. [LM04], [LM06a], [Mey00, Ex. 7.1.17, p. 502] If the eigenvalues of $S_{n\times n}$ are

$$\lambda(S) = \{\underbrace{1, 1, \ldots, 1}_{m-r}, \mu_{m-r+1}, \ldots, \mu_n\}, \quad 1 > |\mu_{m-r+1}| \geq \cdots \geq |\mu_n|,$$

    then the eigenvalues of the Google matrix $G = \alpha S + (1 - \alpha)E$ are

$$\lambda(G) = \{1, \underbrace{\alpha, \ldots, \alpha}_{m-r-1}, (\alpha\mu_{m-r+1}), \ldots, (\alpha\mu_n)\}. \tag{76.3}$$

11. [Mey00] The asymptotic rate of convergence of any aperiodic Markov chain is governed by the magnitude of its largest subdominant eigenvalue. In particular, if the distinct eigenvalues λ_i of an aperiodic chain are ordered $\lambda_1 = 1 > |\lambda_2| \geq |\lambda_3| \geq \cdots \geq |\lambda_n|$, then the number of incorrect digits in each component of $\boldsymbol{\pi}^T(k)$ is eventually going to be reduced by about $-log_{10}|\lambda_2|$ digits per iteration.
12. Determining (or even estimating) $|\lambda_2|$ normally requires substantial effort, but Eq. (76.3) says that $\lambda_2 = \alpha$ for the Google matrix G. This is an extremely happy accident because it means that Google's engineers can completely control the rate of convergence, regardless of the value of the personalization vector $\mathbf{v}^T$ in $E = \mathbf{1}\mathbf{v}^T$.
13. At the last public disclosure Google was setting $\alpha = .85$, so, at this value, the asymptotic rate of convergence of the power method is $-log_{10}(.85) \approx .07$, which means that the power method will eventually take about 14 iterations for each significant place of accuracy that is required.
14. [LM04] Even though they can control the rate of convergence with α, Google's engineers are forced to perform a delicate balancing act because while decreasing α increases the rate of convergence, decreasing α also lessens the effect of the true hyperlink structure of the Web, which is Google's primary mechanism for measuring Web page importance. Increasing α more accurately reflects the Web's true link structure, but, along with slower convergence, sensitivity issues begin to surface in the sense that slightly different values for α near 1 can produce significantly different PageRanks.
15. [KHM03a] The power method can be substantially accelerated by a quadratic extrapolation technique similar to Aitken's Δ^2 method, and there is reason to believe that Google has adopted this procedure.
16. [KHM03b], [KHG04] Other improvements to the basic power method include a block algorithm and an adaptive algorithm that monitors the convergence of individual elements of the PageRank vector. As soon as components of the vector have converged to an acceptable tolerance, they are no longer computed. Convergence is faster because the work per iteration decreases as the process evolves.
17. [LM02], [LM04], [LM06b], [LGZ03] Other methods partition H into two groups according to dangling nodes and nondangling nodes. The problem is then aggregated by lumping all of the dangling nodes into one super state to produce a problem that is significantly reduced in size — this is due to the fact that the dangling nodes account for about one fourth of the Web's nodes. The most exciting feature of all these

algorithms is that they do not compete with one another. In fact, it is possible to combine some of these algorithms to achieve even greater performance.

18. The accuracy of PageRank computations is an important implementation issue, but we do not know the accuracy with which Google works. It seems that it must be at least high enough to differentiate between the often large list of ranked pages that Google usually returns, and since $\boldsymbol{\pi}^T$ is a probability vector containing $O(10^9)$ components, it is reasonable to expect that accuracy giving at least ten significant places is needed to distinguish among the elements.
19. A weakness of PageRank is "topic drift." The PageRank vector might be mathematically accurate, but this is of little consequence if the results point the user to sites that are off-topic. PageRank is a query-independent measure that is essentially determined by a popularity contest with everyone on the Web having a vote, and this tends to skew the results in the direction of importance (measured by popularity) over relevance to the query. This means that PageRank may have trouble distinguishing between pages that are authoritative in general and pages that are authoritative more specifically to the query topic. It is believed that Google engineers devote much effort to mitigate this problem, and this is where the metrics that determine the content score might have an effect.
20. In spite of topic drift, Google's decision to measure importance by means of popularity over relevance turned out to be the key to Google's success and the source of its strength. The query-dependent measures employed by Google's predecessors were major stumbling blocks in maintaining query processing speed as the Web grew. PageRank is query-independent, so at query time only a quick lookup into an inverted file storage is required to determine pertinent pages, which are then returned in order by the precomputed PageRanks. The small compromise of topic drift in favor of processing speed won the day.
21. A huge advantage of PageRank is its virtual imperviousness to spamming (artificially gaming the system). High PageRank is achieved by having many inlinks from highly ranked pages, and while it may not be so hard for a page owner to have many of his cronies link to his page, it is difficult to generate a lot of inlinks from *important* sites that have a high rank.
22. [TM03] Another strength of PageRank concerns the flexibility of the "personalization" (or "intervention") vector $\mathbf{v}^T$ that Google is free to choose when defining the perturbation term $E = \mathbf{1}\mathbf{v}^T$. The choice of $\mathbf{v}^T$ affects neither mathematical nor computational aspects, but it does alter the rankings in a predictable manner. This can be a terrific advantage if Google wants to intervene to push a site's PageRank down or up, perhaps to punish a suspected "link farmer" or to reward a favored client. Google has claimed that it does not make a practice of rewarding favored clients, but it is known that Google is extremely vigilant and sensitive concerning people who try to manipulate PageRank, and such sites are punished. However, the outside world is not privy to the extent to which either the stick or carrot is employed.
23. [FLM04], [KH03], [KHG04], [KHM03a], [LM04], [LM06a], [LGZ03], [LM03], [NZJ01] In spite of the simplicity of the basic concepts, subtle issues such as personalization, practical implementations, sensitivity, and updating lurk just below the surface.
24. We have summarized only the mathematical component of Google's ranking system, but, as mentioned earlier, there are 100 or more nonmathematical content metrics that are also considered when Google responds to a query. The results seen by a user are in fact PageRank tempered by these other metrics. While Google is secretive about most of its other metrics, it has made it clear that the other metrics are subservient to its mathematical PageRank scores.

A signal is a function of time, depending on either a continuous, real time variable or a discrete integer time variable. Signal processing is a collection of diverse mathematical, statistical, and computational techniques for transforming, extracting information from, and modeling of signals. Common signal processing techniques include filtering a signal to remove undesired frequency components, extracting a model that describes key features of a signal, estimation of the frequency components of a signal, prediction of the future behavior of a signal from past data, and finding the direction from which a signal arrives at an array of sensors.

Many modern methods for signal processing have deep connections to linear algebra. Rather than attempting to give a complete overview of such a diverse field, we survey a selection of contemporary methods for the processing of discrete time signals with deep connections to matrix theory and numerical linear algebra. These topics include linear prediction, Wiener filtering, spectral estimation, and direction of arrival estimation. Notable ommissions include classical methods of filter design, the fast Fourier transform (FFT), and filter structures. (See Chapter 81.)

77.1 Basic Concepts

We begin with basic definitions which are standard and can be found in [PM96].

Definitions:

A **signal** $\boldsymbol{x}$ is a real sequence with element k of the sequence for $k = 0, \pm 1, \pm 2, \dots$ given by $x(k)$. The set of all signals is a vector space with the sum $\boldsymbol{w} = \boldsymbol{x} + \boldsymbol{y}$ defined by $w(k) = x(k) + y(k)$ and the scalar product $\boldsymbol{v} = a\boldsymbol{x}$ where a is a real scalar given by $v(k) = ax(k)$.

A **linear time-invariant system** is a mapping $L(\boldsymbol{x}) = \boldsymbol{y}$ of an input signal $\boldsymbol{x}$ to an output signal $\boldsymbol{y}$ that satisfies the following properties:

1. Linearity: If $L(\boldsymbol{x}_0) = \boldsymbol{y}_0$ and $L(\boldsymbol{x}_1) = \boldsymbol{y}_1$, then $L(a\boldsymbol{x}_0 + b\boldsymbol{y}_0) = a\boldsymbol{y}_0 + b\boldsymbol{y}_1$ for any $a, b \in \mathbb{R}$.
2. Time-invariance: If $L(\boldsymbol{x}) = \boldsymbol{y}$ and $\hat{\boldsymbol{x}}$ is a shifted version of $\boldsymbol{x}$ given by $\hat{x}(k) = x(k - k_0)$, then $L(\hat{\boldsymbol{x}}) = \hat{\boldsymbol{y}}$ where $\hat{y}(k) = y(k - k_0)$. That is, shifted inputs lead to correspondingly shifted outputs.

The **impulse response** of a linear time-invariant system is the output $\boldsymbol{h}$ that results from applying as input the unit impulse $\boldsymbol{\delta}$ where $\delta(0) = 1$ and $\delta(k) = 0$ for $k \neq 1$.

The **convolution** $\boldsymbol{y}$ of $\boldsymbol{h}$ and $\boldsymbol{x}$ is written $\boldsymbol{y} = \boldsymbol{h} * \boldsymbol{x}$ and is defined by the sum

$$y(k) = \sum_{j=-\infty}^{\infty} h(j)x(k-j).$$

A signal $\boldsymbol{x}$ is **causal** if $x(k) = 0$ for $k < 0$.

A linear time-invariant system is **causal** if every causal input gives a causal output. An equivalent definition is that a system is **causal** if its impulse response sequence is causal.

The **z-transform** of a signal or impulse response $\boldsymbol{x}$ is

$$X(z) = \sum_{k=-\infty}^{\infty} x(k)z^{-k}$$

where $X(z)$ is defined in the region of convergence of the sum.

The **transfer function** of a linear system with impulse response $\boldsymbol{h}$ is the z-transform of the impulse response

$$H(z) = \sum_{k=-\infty}^{\infty} h(k)z^{-k}.$$

The **discrete time Fourier transform** of $\boldsymbol{x}$ is the function of ω obtained by evaluating the z-transform on the unit circle

$$X(e^{i\omega}) = \sum_{k=-\infty}^{\infty} x(k)e^{-i\omega k}.$$

If $\boldsymbol{x}$ is an impulse response of a system, then $X(e^{i\omega})$ is the **frequency response** of the system. The discrete time Fourier transform is defined only if the region of convergence of the z-transform includes the unit circle.

A filter is **minimum phase** if the zeros of the transfer function are in the unit circle.

A **finite impulse response** (FIR) filter is a system that maps an input signal $\boldsymbol{x}$ to an output signal $\boldsymbol{y}$ through the sum

$$y(k) = \sum_{j=0}^{n-1} b(j)x(k-j).$$

A rational **infinite impulse response** (IIR) filter is a causal system that maps inputs $\boldsymbol{x}$ to outputs $\boldsymbol{y}$ via a relation of the form

$$y(k) = \sum_{j=0}^{n-1} b(j)x(k-j) - \sum_{j=1}^{m} a(j)y(k-j).$$

Causality is an essential part of the definition; without this assumption the above relation does not uniquely define a mapping from inputs to outputs.

A signal $\boldsymbol{x}$ has **finite energy** if

$$\sum_{k=-\infty}^{\infty} |x(k)|^2 < \infty.$$

A system mapping input $\boldsymbol{x}$ to output $\boldsymbol{y}$ is **stable** if $|x(k)| < B_x$ for $0 < B_x < \infty$ and for all k implies that there is $0 < B_y < \infty$ such that the output satisfies $|y(k)| < B_y$ for all k.

Facts:

1. The impulse response $\boldsymbol{h}$ uniquely determines a linear time-invariant system. The mapping from the input $\boldsymbol{x}$ to the output $\boldsymbol{y}$ is given by $\boldsymbol{y} = \boldsymbol{h} * \boldsymbol{x}$. Convolution is commutative so that if $\boldsymbol{y} = \boldsymbol{g} * (\boldsymbol{h} * \boldsymbol{x})$, then $\boldsymbol{y} = \boldsymbol{h} * (\boldsymbol{g} * \boldsymbol{x})$. Thus, the order in which two linear time-invariant filters are applied to a signal does not matter.
2. A causal system can be applied in real time in the sense that output $y(k)$ can be computed from the convolution $\boldsymbol{y} = \boldsymbol{h} * \boldsymbol{x}$ as soon as $x(k)$ is available.
3. A system defined by its impulse response $\boldsymbol{h}$ is stable if and only if
$$\sum_{k=-\infty}^{\infty} |h(k)| < \infty.$$
4. An expression for the z-transform of a signal (or an impulse response) does not uniquely determine the signal. It is also necessary to know the region of convergence. If $X(z)$ is the z-transform of $\boldsymbol{x}$, then the inverse transform is
$$x(k) = \frac{1}{2\pi i} \oint X(z) z^{k-1}\, dz$$
where the integral is taken over any contour enclosing the origin and in the region where $X(z)$ is analytic. A system is uniquely determined by its transfer function and the region of convergence of the transfer function.
5. An FIR filter has impulse response
$$h(k) = \begin{cases} b(k) & \text{for } 0 \leq k \leq n-1 \\ 0 & \text{otherwise.} \end{cases}$$
6. An FIR filter has transfer function
$$H(z) = b(0) + b(1)z^{-1} + \cdots + b(n-1)z^{-(n-1)}.$$
7. The impulse response $\boldsymbol{h}$ of a causal IIR filter is the unique solution to the recurrence
$$h(k) = \begin{cases} 0 & k \leq 0 \\ b(k) - \sum_{j=1}^{m} a(j)h(k-j) & 0 \leq k \leq n-1 \\ -\sum_{j=1}^{m} a(j)h(k-j) & k \geq n \end{cases}.$$
This recurrence uniquely determines a causal impulse response $\boldsymbol{h}$ and, hence, uniquely determines the mapping from inputs to outputs.
8. A rational IIR filter has transfer function
$$H(z) = \frac{b(0) + b(1)z^{-1} + \cdots + b(n-1)z^{-(n-1)}}{1 + a(1)z^{-1} + \cdots + a(m)z^{-m}}.$$
9. A linear time-invariant system with input $\boldsymbol{x}$ and impulse response $\boldsymbol{h}$ with z-transform $X(z)$ and transfer function $H(z)$ has output $\boldsymbol{y}$ with z-transform
$$Y(z) = H(z)X(z).$$
10. A discrete version of the Paley–Wiener theorem states that $\boldsymbol{x}$ is causal and has finite energy if and only if the corresponding z-transform $X(z)$ is analytic in the exterior of the unit circle and
$$\sup_{1<r<\infty} \int_{-\pi}^{\pi} \left|X(re^{i\omega})\right|^2 d\omega < \infty.$$

If $|X(e^{i\omega})|$ is square integrable, then $|X(e^{i\omega})|$ is the Fourier transform of some causal system finite energy signal if and only if

$$\int_{-\pi}^{\pi} \left|\ln\left(|X(e^{i\omega})|\right)\right| \, d\omega < \infty.$$

11. For rational transfer functions $H(z)$ corresponds to a causal stable system if and only if the poles of $H(z)$ are in the unit circle. Thus, FIR filters are always stable and IIR filters are stable when the poles of the transfer function are in the unit circle.
12. A filter that is minimum phase has a causal stable inverse filter with transfer function $G(z) = 1/H(z)$. That is, filtering a signal $\boldsymbol{x}$ by a filter with z-transform $H(z)$ and then by a filter with z-transform $G(z)$ gives an output with z-transform $G(z)H(z)X(z) = X(z)$. The minimum phase property is of particular significance since the only filters that can be applied in real time and without excessive growth of errors due to noise are those that are causal and stable. In most circumstances only minimum phase filters are invertible in practice.

Examples:

1. The causal impulse response $\boldsymbol{h}$ with $h(k) = a^k$ for $k \geq 0$ and $h(k) = 0$ for $k < 0$ has z-transform $H(z) = 1/(1 - az^{-1})$ with region of convergence $|z| > |a|$. The anticausal impulse response $\hat{\boldsymbol{h}}$ with $\hat{h}(k) = -a^k$ for $k < 0$ and $\hat{h}(k) = 0$ for $k \geq 0$ has z-transform $H(z) = 1/(1 - az^{-1})$ with region of convergence $|z| < |a|$.
2. The causal impulse response $\boldsymbol{h}$ with

$$h(k) = \begin{cases} 2^{-k} + 3^{-k} & \text{for } k \geq 0 \\ 0 & k < 0 \end{cases}$$

has z-transform

$$H(z) = \frac{1}{1 - (2z)^{-1}} + \frac{1}{1 - (3z)^{-1}} = \frac{2 - \frac{5}{6}z^{-1}}{1 - \frac{5}{6}z^{-1} + \frac{1}{6}z^{-2}}$$

with region of convergence $|z| > 1/2$. The impulse response can be realized by a rational IIR filter of the form

$$y(k) = 2x(k) - \frac{5}{6}x(k-1) + \frac{5}{6}y(k-1) + \frac{1}{6}y(k-2).$$

The zeros of $z^2 - (5/6)z + (1/6)$ are 1/2 and 1/3 so that the system is stable.

77.2 Random Signals

Definitions of statistical terms can be found in Chapter 70.

Definitions:

A **random signal** or **random process** $\boldsymbol{x}$ is a sequence $x(k)$ of real random variables indexed by $k = 0, \pm 1, \pm 2, \ldots$.

A random signal $\boldsymbol{x}$ is **wide-sense stationary** (for brevity, we will use **stationary** to mean the same thing) if the mean $\mu_x = E[x(k)]$ and **autocorrelation sequence** $r_{xx}(k) = E[x(j)x(j-k)]$ do not depend on j. We assume that all random signals are wide-sense stationary. Two stationary random signals $\boldsymbol{x}$ and $\boldsymbol{y}$ are jointly stationary if the **cross-correlation** sequence $r_{yx}(k) =$

$E\left[y(j)x(j-k)\right]$ does not depend on j. When referring to two stationary signals, we always assume that the signals are jointly stationary as well.

A sequence $\mathbf{x}(k)$ of real random $n \times 1$ vectors indexed by $k = 0, \pm 1, \pm 2, \ldots$ is **stationary** if $E\left[\mathbf{x}(k)\right]$ and $E[\mathbf{x}(k)\mathbf{x}^{\mathrm{T}}(k)]$ do not depend on k.

The **autocorrelation matrix** of a sequence of stationary random vectors $\mathbf{x}(k)$ is

$$R_{\mathbf{x}} = E\left[\mathbf{x}(k)\mathbf{x}^{\mathrm{T}}(k)\right].$$

A zero mean stationary random signal $\boldsymbol{n}$ is a **white noise process** if it has autocorrelation sequence

$$r_{nn}(j) = E\left[n(k)n(k-j)\right] = \begin{cases} \sigma_n^2 & j = 0 \\ 0 & j \neq 0 \end{cases}$$

where σ_n^2 is the **variance** of $\boldsymbol{n}$.

A white noise driven **autoregressive process** (AR process) $\boldsymbol{x}$ is of the form

$$x(k) = n(k) - \sum_{j=1}^{n} a(j)x(k-j)$$

where $\boldsymbol{n}$ is a white noise process and the filtering of $\boldsymbol{n}$ to obtain $\boldsymbol{x}$ is causal.

Given a signal $\boldsymbol{x}$, we denote the z-transform of the autocorrelation sequence of $\boldsymbol{x}$ by $S_x(z)$. The **spectral density** of a stationary random signal $\boldsymbol{x}$ with autocorrelation sequence $r_{xx}(k)$ is the function of ω given by evaluating $S_x(z)$ on the unit circle

$$S_x(e^{i\omega}) = \sum_{j=-\infty}^{\infty} r_{xx}(j)e^{-ij\omega}.$$

A random signal with spectral density $S_x(e^{i\omega})$ is **bandlimited** if $S_x(e^{i\omega}) = 0$ on a subset of $[-\pi, \pi]$ of nonzero measure.

A random signal with spectral density $S_x(e^{i\omega})$ has **finite power** if

$$\int_{-\pi}^{\pi} S_x(e^{i\omega})\, d\omega < \infty.$$

The **spectral factorization**, when it exists, of a spectral density $S_x(z)$ is a factorization of the form

$$S_x(z) = L(z)\overline{L(\overline{z^{-1}})}$$

where $L(z)$ and $1/L(z)$ are both analytic for $|z| > 1$. Interpreted as transfer functions $L(z)$ and $1/L(z)$ both describe causal, stable systems. That is, $L(z)$ is causal and stable and causally and stably invertible.

Facts:

1. If $\mathbf{x}(k)$ is a sequence of vectors obtained by sampling a random sequence of vectors, then under suitable ergodicity assumptions

$$R_{\mathbf{x}} = \lim_{n\to\infty} \frac{1}{n} \sum_{k=0}^{n} \mathbf{x}(k)\mathbf{x}^{\mathrm{T}}(k).$$

In computational practice $R_{\mathbf{x}}$ is often estimated using a truncated sum in which n is finite.

2. The expectation $\langle x, y\rangle = E\left[xy\right]$ can be viewed as an inner product on a real Hilbert space of zero mean random variables with $E[|x|^2] < \infty$. This gives many results in optimal filtering a geometric interpretation in terms of orthogonalization and projection on the span of a set of random variables in a way that is perfectly analogous to least squares problems in any other Hilbert space. From this point of view, a white noise process $\boldsymbol{n}$ is a sequence of orthogonal random variables.
3. If a random signal $\boldsymbol{x}$ with autocorrelation sequence $\boldsymbol{r}_x$ is passed through a system with impulse response $\boldsymbol{h}$, then the output $\boldsymbol{y}$ has autocorrelation

$$\boldsymbol{r}_y = \boldsymbol{h} * \boldsymbol{r}_x * \tilde{\boldsymbol{h}}$$

   where $\tilde{\boldsymbol{h}}$ is defined by $\tilde{h}(j) = h(-j)$.
4. The spectral density is nonnegative, $S_x(e^{i\omega}) \geq 0$.
5. The spectral density of white noise is $S_n(e^{i\omega}) = \sigma_n^2$.
6. [Pap85] If a random signal $\boldsymbol{x}$ with spectral density $S_x(z)$ passes through a filter with transfer function $H(z)$, then the output $\boldsymbol{y}$ is a stationary signal with

$$S_y(z) = S_x(z)H(z)\overline{H(\overline{z^{-1}})} \qquad \text{or} \qquad S_y(e^{i\omega}) = S_x(e^{i\omega})|H(e^{i\omega})|^2.$$

7. If $L(z)$ is the spectral factor of $S_x(z)$, then on the unit circle we have $S_x(e^{iw}) = |L(e^{iw})|^2$.
8. [SK01], [GS84] The spectral factorization exists if and only if the signal has finite power and satisfies

$$\int_{-\pi}^{\pi} \ln\left(S_x(e^{i\omega})\right)\, d\omega > -\infty.$$

   If $S_x(e^{i\omega})$ is zero on a set of nonzero measure, then the condition is not satisfied. Thus, bandlimited signals do not have a spectral factorization.
9. If a spectral factor $L(z)$ exists for a signal $\boldsymbol{x}$ with spectral density $S_x(e^{i\omega})$ and

$$L(z) = \sum_{k=0}^{\infty} l(k)z^{-k} \qquad \text{and} \qquad M(z) = \frac{1}{L(z)} = \sum_{k=0}^{\infty} m(k)z^{-k},$$

   then the filtered signal $\boldsymbol{n} = \boldsymbol{m} * \boldsymbol{x}$ given by

$$n(k) = \sum_{j=0}^{\infty} m(j)x(k-j)$$

   is a white noise process with $S_n(e^{i\omega}) = 1$. The original signal can be obtained by causally and stably filtering $\boldsymbol{n}$ with $\boldsymbol{l}$:

$$x(k) = \sum_{j=0}^{\infty} l(j)n(k-j).$$

   The signal $\boldsymbol{n}$ is the **innovations** process for $\boldsymbol{x}$ and the representation of $\boldsymbol{x}$ through filtering $\boldsymbol{n}$ by $\boldsymbol{l}$ is the **innovations representation** for $\boldsymbol{x}$. It is a model of $\boldsymbol{x}$ as a filter driven by white noise. The innovations representation is an orthogonalization of the sequence of random variables $\boldsymbol{x}$. The innovations representation for x is analogous to the QR factorization of a matrix.

Examples:

1. For a white noise process $\boldsymbol{n}$ with variance $\sigma_n^2 = 1$, define the autoregressive process $\boldsymbol{x}$ by

$$x(k) = n(k) + ax(k-1)$$

where $|a| < 1$. The impulse response and transfer function of the IIR filter generating $\boldsymbol{x}$ are

$$h(k) = \begin{cases} 0 & k < 0 \\ a^k & k \geq 0 \end{cases}, \qquad \text{and} \qquad H(z) = \frac{1}{1 - az^{-1}}.$$

The autocorrelation sequence for $\boldsymbol{x}$ is the sequence $\boldsymbol{r}_{xx}$ given by

$$r_{xx}(k) = \frac{1}{1-a^2} a^{|k|}.$$

The autocorrelation sequence has z-transform

$$S_x(z) = \frac{1}{(1 - az^{-1})(1 - az)}$$

so that the spectral density is

$$S_x(e^{i\omega}) = \frac{1}{1 + a^2 - 2a\cos(\omega)}.$$

The spectral factor is

$$L(z) = \frac{1}{1 - az^{-1}}.$$

77.3 Linear Prediction

Definitions:

The **linear prediction** problem is to find an estimate $\hat{\boldsymbol{x}}$ of a stationary random signal $\boldsymbol{x}$ as a linear combination

$$\hat{x}(k) = \sum_{j=1}^{\infty} a(j)x(k-j),$$

with the $a(j)$ chosen to minimize the **mean square prediction error** $E_\infty = E[|e(k)|^2]$ where $e(k) = \hat{x}(k) - x(k)$ is the **prediction error**. Thus, the goal is to find a current estimate $\hat{x}(k)$ of $x(k)$ from the past values $x(k-1), x(k-2), \ldots$.

A random signal is **predictable** if $E_\infty = 0$. A signal that is not predictable is **regular**.

The **order** n **linear prediction problem** is to find an estimate of a stationary random signal $\boldsymbol{x}$ with a signal $\hat{\boldsymbol{x}}$ of the form $\hat{x}(k) = \sum_{j=1}^{n} a_n(j)x(k-j)$ so as to minimize the mean square error $E_n = E[|e(k)|^2]$ where $e(k) = \hat{x}(k) - x(k)$.

A random signal is **order** n **predictable** if $E_n = 0$.

The **prediction error filter** and the **order** n **prediction error filter** are the filters with transfer functions

$$E(z) = 1 - \sum_{j=1}^{\infty} a(j)z^{-j}$$

and

$$E_n(z) = 1 - \sum_{j=1}^{n} a_n(j)z^{-j}.$$

The **Wiener–Hopf equations** for the optimal prediction coefficients $a(j)$ are

$$r_{xx}(l) = \sum_{j=1}^{\infty} a(j) r_{xx}(l-j)$$

for $l \geq 1$.

Given a random signal $x(k)$ with autocorrelation $r_{xx}(k)$, the optimal prediction coefficients $a^{(n)}(j)$ and mean square prediction error E_n that satisfy the **Yule–Walker equations** are

$$\begin{bmatrix} r_{xx}(0) & r_{xx}(1) & \cdots & r_{xx}(n) \\ r_{xx}(1) & r_{xx}(0) & \ddots & \vdots \\ \vdots & \ddots & \ddots & r_{xx}(1) \\ r_{xx}(n) & \cdots & r_{xx}(1) & r_{xx}(0) \end{bmatrix} \begin{bmatrix} 1 \\ -a_n(1) \\ \vdots \\ -a_n(n) \end{bmatrix} = \begin{bmatrix} E_n \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

or $T_n \mathbf{a}_n = E_n \mathbf{e}_1$.

The **Levinson–Durbin algorithm** for the computation solution of the order n linear prediction problem is

$$\mathbf{a}_n = \begin{bmatrix} \mathbf{a}_{n-1} \\ 0 \end{bmatrix} + \gamma_n \begin{bmatrix} 0 \\ R\mathbf{a}_{n-1} \end{bmatrix}$$

where R is the permutation that reverses the order of the elements of $\mathbf{a}_{n-1}$. The quantity γ_n is computed from the relation

$$\gamma_n = -\frac{r_{xx}(n) - \sum_{j=1}^{n-1} a_{n-1}(j) r_{xx}(n-j)}{E_{n-1}}$$

and the mean square prediction error is computed from $E_n = E_{n-1}(1 - |\gamma_n|^2)$. The algorithm starts with $E_0 = r_{xx}(0)$ and $\mathbf{a}_0 = 1$. If $x(k)$ is order n predictable, then the process terminates with the order n predictor and $E_n = 0$.

The parameters γ_k are known as **reflection coefficients**, **partial correlation coefficients**, or **Schur parameters**. The **complementary parameters** are $\delta_k = \sqrt{1 - |\gamma_k|^2}$.

Facts:

1. [Pap85] The Wold decomposition theorem: Every stationary random signal can be represented as the sum of a regular and a predictable signal

   $$x(k) = x_r(k) + x_p(k).$$

   The two components are orthogonal with $E[x_r(k)x_p(k)] = 0$.
2. [Pap85] The Wiener–Hopf equations can be interpreted as stating that the prediction error $\hat{x}(k) - x(k)$ is orthogonal to $x(k-l)$ for $l \geq 1$ in the inner product $\langle x, y \rangle = E[xy]$.
3. The Toeplitz matrix T_n in the Yule–Walker equations is positive semidefinite.
4. The Levinson–Durbin algorithm is an $O(n^2)$ order recursive method for solving the linear prediction problem. In most cases the numerical results from applying the algorithm are comparable to the numerically stable Cholesky factorization procedure [Cyb80]. An alternative fast method, the Schur algorithm, computes a Cholesky factorization and can be proven to be numerically stable [BBH95].
5. The following are equivalent:
   (a) T_{n-1} is positive definite and T_n is positive semidefinite.
   (b) $|\gamma_j| < 1$ for $1 \leq j \leq n-1$ and $|\gamma_n| = 1$.

   (c) $E_j > 0$ for $1 \leq j \leq n-1$ and $E_n = 0$.
   (d) The polynomial $z^n E_n(z)$ has all zeros on the unit circle and each polynomial $z^k E_k(z)$ for $k = 1, 2, \ldots, n-1$ has all zeros strictly inside the unit circle.

6. [Pap85] The prediction errors are monotonic: $E_k \geq E_{k+1}$ and $E_k \to E_\infty \geq 0$ as $k \to \infty$.
7. [SK01] Let

$$a_k(z) = 1 - a_k(1)z - a_k(2)z^2 - \cdots - a_k(k)z^k$$

   where $a_k(j)$ are the prediction coefficients for a signal $\boldsymbol{x}$ with spectral density $S_x(z)$. If $S_x(z) = L(z)\overline{L(\overline{z^{-1}})}$ is the spectral factorization of $S_x(z)$, then

$$L(z) = \lim_{k\to\infty} \frac{E_k^{1/2}}{r_{xx}(0)} \frac{1}{\overline{a_k(\overline{z^{-1}})}}.$$

   A survey, including other representations of the spectral factor and algorithms for computing it, is given in [SK01].
8. [GS84] A finite power random signal $\boldsymbol{x}$ is predictable (i.e., $E_\infty = 0$) if and only if

$$\int_{-\pi}^{\pi} \ln(S_x(e^{i\omega}))\, d\omega > -\infty.$$

   If the signal is regular, then we have the Kolmogorov–Szegö error formula

$$E_\infty = \exp\left(\int_{-\pi}^{\pi} \ln S(e^{i\omega})\, d\omega\right) > 0.$$

Examples:

1. Consider the autoregressive process $\boldsymbol{x}$ given by

$$x(k) = n(k) + ax(k-1)$$

   where $\boldsymbol{n}$ is a white noise process with $\sigma_n^2 = 1$. The solution to the order 1 linear prediction problem is given by the Yule–Walker system

$$\begin{bmatrix} \frac{1}{1-a^2} & \frac{a}{1-a^2} \\ \frac{a}{1-a^2} & \frac{1}{1-a^2} \end{bmatrix} \begin{bmatrix} 1 \\ -a_1(1) \end{bmatrix} = \begin{bmatrix} E_1 \\ 0 \end{bmatrix}.$$

   The Levinson–Durbin algorithm starts with $E_0 = r_{xx}(0) = 1/(1-a^2)$ and $\mathbf{a}_0 = 1$. Thus,

$$\gamma_1 = -\frac{r_{xx}(1)}{E_0} = -\frac{a/(1-a^2)}{1/(1-a^2)} = -a$$

   so that

$$\begin{bmatrix} 1 \\ -a_1(1) \end{bmatrix} = \mathbf{a}_1 = \begin{bmatrix} \mathbf{a}_0 \\ 0 \end{bmatrix} + \gamma_1 \begin{bmatrix} 0 \\ \mathbf{a}_0 \end{bmatrix} = \begin{bmatrix} 1 \\ -a \end{bmatrix}.$$

   Thus, $a_1(1) = a$ and the optimal linear prediction of $x(k)$ from $x(k-1)$ is given by

$$\hat{x}(k) = ax(k-1).$$

   The prediction error is given by

$$E_1 = E[\hat{x}(k) - x(k)] = E[n(k)] = 1.$$

77.4 Wiener Filtering

Linear optimal filtering of stationary signals was introduced by Wiener [Wie49] and Kolmogorov [Kol41]. The material here is covered in books on adaptive filtering [Hay91] and linear estimation [KSH00].

Definitions:

The general **discrete Wiener filtering problem** is the following: Given stationary signals $\boldsymbol{x}$ and $\boldsymbol{y}$ find a filter with impulse response $\boldsymbol{w}$ such that

$$E_w = E\left[\left|y(k) - \sum_{j=-\infty}^{\infty} w(j)x(k-j)\right|^2\right]$$

is minimal. The filter with impulse response $\boldsymbol{w}$ minimizing E_w is the **Wiener filter**. The goal is to approximate a desired signal $\boldsymbol{y}$ by filtering the signal $\boldsymbol{x}$. Equivalently, we seek the best approximation to $y(k)$ in the span of the $x(j)$ for $-\infty < j < \infty$. Note that we leave open the possibility that the Wiener filter is not causal.

Depending on specific relations that may be imposed on $\boldsymbol{y}$ and $\boldsymbol{x}$, the Wiener filtering problem specializes in several important ways: The **Wiener prediction problem** for which $y(k) = x(k+l)$ where $l \geq 1$ and $\boldsymbol{w}$ is assumed causal; the **Wiener smoothing problem** for which $\boldsymbol{y}$ is arbitrary and $\boldsymbol{x}$ is a noise corrupted version of $\boldsymbol{y}$ given by $\boldsymbol{x} = \boldsymbol{y} + \boldsymbol{n}$ where $\boldsymbol{n}$ is the noise; and the **Wiener deconvolution problem** for which we have arbitrary desired signals $\boldsymbol{y}$ and $\boldsymbol{x}$ obtained from $\boldsymbol{y}$ by convolution and the addition of noise, $\boldsymbol{x} = \boldsymbol{h} * \boldsymbol{y} + \boldsymbol{n}$. For the Wiener prediction problem, the goal is to predict future values of $\boldsymbol{x}$ from past values. For the Wiener smoothing problem, the goal is to recover an approximation to a signal $\boldsymbol{y}$ from a noise corrupted version of the signal $\boldsymbol{x}$. For the Wiener deconvolution, the goal is to invert a filter in the presence of noise to obtain the signal $\boldsymbol{y}$ from the filtered and noise corrupted version $\boldsymbol{x}$.

The **FIR Wiener filtering problem** is to choose an FIR filter with impulse response $w(k)$ such that

$$E\left[\left|y(k) - \sum_{j=0}^{n-1} w(j)x(k-j)\right|^2\right]$$

is minimal.

The **causal part** of a signal $x(k)$ is

$$[x(k)]_+ = \begin{cases} x(k) & \text{if } k \geq 0 \\ 0 & \text{if } k < 0 \end{cases} \qquad \text{or} \qquad [X(z)]_+ = \sum_{k=0}^{\infty} x(k)z^{-k}.$$

Facts:

1. The stationarity assumptions ensure that the coefficients $w(j)$ that are used to estimate $y(k)$ from the signal $\boldsymbol{x}$ do not depend on k. That is, the coefficients $w(j)$ that minimize E_w also minimize

$$E\left[\left|y(k-k_0) - \sum_{j=0}^{n-1} w(j)x(k-k_0-j)\right|^2\right]$$

so that the Wiener filter is a linear time invariant system.

2. Let $S_x(z) = L(z)\overline{L(\overline{z^{-1}})}$,

$$r_{yx}(k) = E\left[y(j)x(j-k)\right], \qquad \text{and} \qquad S_{yx}(e^{i\omega}) = \sum_{k=-\infty}^{\infty} r_{yx}(k)e^{ik\omega}.$$

   If we do not require causality, then the Wiener filter has z-transform

$$W(z) = \frac{S_{yx}(z)}{S_{xx}(z)}.$$

   If we do impose causality, then the Wiener filter is

$$\left[\frac{S_{yx}(z)}{L^*(z^{-*})}\right]_+ \frac{1}{L(z)}.$$

3. As seen above, the Wiener filter depends on the cross correlations $r_{yx}(k)$, but not on knowledge of the elements of the unkown sequence $y(k)$. Thus, it is possible to estimate the signal $\boldsymbol{y}$ by filtering $\boldsymbol{x}$ without direct knowledge of $\boldsymbol{y}$. If the autocorrelation sequences $r_{xx}(k)$ and $r_{nn}(k)$ are available (or can be estimated), then $r_{yx}(k)$ can often be computed in a straightforward way. For the Wiener prediction problem, $r_{yx}(k) = r_{xx}(l+k)$. If the noise $\boldsymbol{n}$ and signal $\boldsymbol{y}$ are uncorrelated so that $r_{ny}(k) = 0$ for all k, then for the Wiener smoothing problem $\boldsymbol{r}_{yx} = \boldsymbol{r}_{xx} - \boldsymbol{r}_{nn}$. For the Wiener deconvolution problem, if $\boldsymbol{g}$ is the inverse filter of $\boldsymbol{h}$ and if $\boldsymbol{y}$ and $\boldsymbol{n}$ are uncorrelated, then $\boldsymbol{r}_{yx} = \boldsymbol{g} * (\boldsymbol{r}_{xx} - \boldsymbol{r}_{nn})$.
4. The coefficients for an FIR Wiener filter satisfy the Wiener–Hopf equation

$$\begin{bmatrix} r_{xx}(0) & r_{xx}(-1) & \cdots & r_{xx}(-m+1) \\ r_{xx}(1) & r_{xx}(0) & \ddots & \vdots \\ \vdots & \ddots & \ddots & r_{xx}(-1) \\ r_{xx}(m-1) & \cdots & r_{xx}(1) & r_{xx}(0) \end{bmatrix} \begin{bmatrix} w(0) \\ w(1) \\ \vdots \\ w(m-1) \end{bmatrix} = \begin{bmatrix} r_{yx}(0) \\ r_{yx}(1) \\ \vdots \\ r_{yx}(m-1) \end{bmatrix}.$$

   As with linear prediction, this system of equations can be solved using fast algorithms for Toeplitz systems.

Examples:

1. We consider the first order FIR Wiener prediction problem of predicting $y(k) = x(k+2)$ from the autoregressive process $\boldsymbol{x}$ with $x(k) = n(k) + ax(k-1)$. Thus, we seek $w(0)$ such that

$$E\left[|x(k+2) - w(0)x(k)|^2\right]$$

   is minimal. Since

$$r_{xx}(0) = \frac{1}{1-a^2}$$

   and

$$r_{yx}(0) = r_{xx}(2) = \frac{a^2}{1-a^2}$$

   the Wiener–Hopf equation for $w(0)$ is

$$\frac{1}{1-a^2}w(0) = \frac{a^2}{1-a^2}.$$

77.5 Adaptive Filtering

Definitions:

An FIR **adaptive filter** is a filter with coefficients that are updated to match the possibly changing statistics of the input $\boldsymbol{x}$ and the desired output $\boldsymbol{y}$. The output is

$$\hat{y}(k) = \sum_{j=0}^{m-1} w_k(j)x(k-j)$$

where the $w_k(j)$ depend on k. The goal is similar to that of the Wiener filter, that is, to approximate the sequence $\boldsymbol{y}$. The difference is that instead of computing a fixed set of coefficients $w(j)$ from knowledge of the statistics of stationary signals $\boldsymbol{x}$ and $\boldsymbol{y}$, the coefficients are allowed to vary with k and are computed from actual samples of the sequences $\boldsymbol{x}$ and $\boldsymbol{y}$.

A **recursive least squares (RLS)** adaptive FIR filter is a rule for updating the coefficients $w_k(j)$. The coefficients are chosen to minimize

$$\min_{\mathbf{w}_k} \left\| D_{\rho,k} \begin{bmatrix} x(l) & x(l-1) & \cdots & x(l-m+1) \\ x(l+1) & x(l) & \cdots & x(l-m+2) \\ \vdots & \ddots & \ddots & \vdots \\ x(k) & x(k-1) & \cdots & x(k-m+1) \end{bmatrix} \begin{bmatrix} w_k(0) \\ w_k(1) \\ \vdots \\ w_k(m-1) \end{bmatrix} - D_{\rho,k} \begin{bmatrix} y(l) \\ y(l+1) \\ \vdots \\ y(k) \end{bmatrix} \right\|_2$$

where $k \geq l+m-1$ and $D_{\rho,k} = \operatorname{diag}(\rho^{k-l}, \rho^{k-l-1}, \ldots \rho^0)$ with $0 < \rho \leq 1$. Equivalently, the vector $\mathbf{w}_k$ is chosen to solve $\min_{\mathbf{w}_k} \|D_{\rho,k}T_{l,k}\mathbf{w}_k - D_{\rho,k}\mathbf{y}_k\|$. The parameter ρ is chosen to decrease the influence of older data. This is of use when the signals $\boldsymbol{x}$ and $\boldsymbol{y}$ are only approximately stationary, i.e., their statistical properties are slowly time varying.

A signal $\boldsymbol{x}$ is **persistently exciting of order m** if there exist $c_1 > 0$, $c_2 \geq c_1$, and j such that

$$c_1 I \leq \lambda_p \left(\frac{1}{k-l+1} T_{l,k}^{\mathrm{T}} T_{l,k} \right) \leq c_2 I$$

for each eigenvalue λ_p of $T_{l,k}^{\mathrm{T}} T_{l,k}/(k-l+1)$ and for all $k \geq j$.

Facts:

1. The vector $\mathbf{w}_k$ can be updated using the following recursive formulas:

$$\mathbf{w}_k = \mathbf{w}_{k-1} + \mathbf{g}_k \left(y(k) - \mathbf{w}_{k-1}^{\mathrm{T}} \mathbf{x}_k \right)$$

where

$$\mathbf{x}_k = \begin{bmatrix} x(k) \\ \vdots \\ x(k-m+1) \end{bmatrix},$$

$$\mathbf{g}_k = \frac{\rho^{-2} P_{k-1} \mathbf{x}_k}{1 + \rho^{-2} \mathbf{x}_k^{\mathrm{T}} P_{k-1} \mathbf{x}_k},$$

with

$$P_k = \rho^{-2} P_{k-1} - \rho^{-2} \mathbf{g}_k \mathbf{x}_k^{\mathrm{T}} P_{k-1}.$$

With initialization $P_k = (T_{l,k}^{\mathrm{T}} D_{\rho,k}^2 T_{l,k})^{-1}$ and $\mathbf{w}_k = P_k T_{l,k}^{\mathrm{T}} D_{\rho,k}^2 \mathbf{y}_k$, the recurrences compute the solution $\mathbf{w}_k$ to the recursive least squares problem.

2. [GV96] The weight vector $\mathbf{w}_k$ can also be updated as k increases with an $O(n^2)$ cost using a standard QR updating algorithm. Such algorithms have good numerical properties.
3. If $\boldsymbol{x}$ and $\boldsymbol{y}$ are stationary, if $\rho = 1$, and if $\boldsymbol{x}$ is persistently exciting, then $\mathbf{w}_k$ converges to the Wiener filter as $k \to \infty$. Under these assumptions the effect of initializing P_k incorrectly becomes negligible as $k \to \infty$. Thus, convergence does not depend on the correct initialization of $P_k = T_{l,k}^{\mathrm{T}} T_{l,k}$. For simplicity, it is common to choose an initial P_k that is a multiple of the identity.
4. If $\boldsymbol{x}$ and $\boldsymbol{y}$ are not stationary, then ρ is typically chosen to be less than one in order to allow the filter to adapt to changing statistics. If the signals really are stationary, then choice of $\rho < 1$ sacrifices convergence of the filter.
5. There are a variety of algorithms that exploit the Toeplitz structure of the least squares problem, reducing the cost per update of $\mathbf{w}_k$ to $O(n)$ operations [CK84]. An algorithm that behaves well in finite precision is analyzed in [Reg93].

Examples:

1. Consider applying a recursive least squares adaptive filter to signals $\boldsymbol{x}$ and $\boldsymbol{y}$ with

$$x(1) = 1, x(2) = 2, x(3) = 3, x(4) = 4$$

and

$$y(2) = 5, y(3) = 6, y(4) = 8.$$

The vector of filter coefficients $\mathbf{w}_3$ satisfies

$$\begin{bmatrix} 2 & 1 \\ 3 & 1 \end{bmatrix} \mathbf{w}_3 = \begin{bmatrix} 5 \\ 6 \end{bmatrix},$$

so that

$$\mathbf{w}_3 = \begin{bmatrix} 4 \\ -3 \end{bmatrix}.$$

We also have

$$P_3 = \left(\begin{bmatrix} 2 & 1 \\ 3 & 1 \end{bmatrix}^{\mathrm{T}} \begin{bmatrix} 2 & 1 \\ 3 & 1 \end{bmatrix} \right)^{-1} = \begin{bmatrix} 13 & 8 \\ 8 & 5 \end{bmatrix},$$

so that

$$\mathbf{g}_4 = \frac{P_3 \mathbf{x}_4}{1 + \mathbf{x}_4^{\mathrm{T}} P_3 \mathbf{x}_4} = \frac{1}{6} \begin{bmatrix} -4 \\ 7 \end{bmatrix}.$$

Thus, the next coefficient vector $\mathbf{w}_4$ is

$$\mathbf{w}_4 = \mathbf{w}_3 + \mathbf{g}_3 \big(y(4) - \mathbf{w}_3^{\mathrm{T}} \mathbf{x}_4 \big) = \begin{bmatrix} 10/3 \\ -11/6 \end{bmatrix}.$$

The process can be continued by updating P_4, $\mathbf{g}_5$, and $\mathbf{w}_5$.

77.6 Spectral Estimation

Definitions:

The **deterministic spectral estimation** problem is to estimate the spectral density $S_x(e^{i\omega})$ from a finite number of correlations $r_{xx}(k)$ for $0 \leq k \leq n$. Note that this definition is not taken to imply that the signal $\boldsymbol{x}$ is deterministic, but that the given data are correlations rather than samples of the random signals.

The **stochastic spectral estimation** problem is to estimate $S(e^{i\omega})$ from samples of the random signal $x(k)$ for $0 \leq k \leq n$.

The problem of estimating **sinusoids in noise** is to find the frequencies ω_j of

$$\hat{x}(k) = \alpha_1 \cos(\omega_1 k + \eta_1) + \alpha_2 \cos(\omega_2 k + \eta_2) + \cdots + \alpha_p \cos(\omega_p k + \eta_p) + w(k) = x(k) + n(k)$$

where $\boldsymbol{n}$ is zero mean white noise with variance σ_n^2 and $\boldsymbol{x}$ is the exact sinusoidal signal with random frequencies $\omega_j \in [0, 2\pi)$ and phases η_j. The frequencies and phases are assumed to be uncorrelated with the noise $\boldsymbol{n}$. The available data can be the samples of the signal $\boldsymbol{x}$ or the autocorrelation sequence $r_{xx}(j)$.

Facts:

1. [PM96] A traditional method for the deterministic spectral estimation problem is to assume that any $r_{xx}(j)$ not given are equal to zero. When additional information is available in the form of a signal model, it is possible to do better by extending the autocorrelation sequence in a way that is consistent with the model.
2. [Pap85] The method of maximum entropy: The sequence $r_{xx}(k)$ is extended so as to maximize the entropy rate
$$\int_{-\pi}^{\pi} \ln S(e^{i\omega})\, d\omega,$$
where it is assumed that the random signal $\boldsymbol{x}$ is a sequence of normal random variables. It can be shown that the spectrum that achieves this is the spectrum of an autoregressive signal
$$S(e^{i\omega}) = \frac{E_n}{\left|1 - \sum_{j=1}^{n} a_n(j) e^{-i\omega j}\right|^2},$$
where the $a_n(j)$ are the coefficients obtained from the Yule–Walker equations.
3. [Pis73] Pisarenko's method: Given a signal comprised of sinusoids in noise, if $\sigma_n = 0$, then the signal sequence $\boldsymbol{x}$ is order p predictable and the signal and its autocorrelation sequence $\boldsymbol{r}_{xx}$ satisfy
$$x(k) = a(1)x(k-1) + a(2)x(k-2) + \cdots + a(p)x(k-p),$$
$$r_{xx}(k) = a(1)r(k-1) + a(2)r_{xx}(k-2) + \cdots + a(p)r_{xx}(k-p),$$
where $\mathbf{a}_p = \begin{bmatrix} 1 & -a_p(1) & \cdots & -a_p(p) \end{bmatrix}^{\mathrm{T}}$ is a null vector of the $(p+1)\times(p+1)$ autocorrelation matrix $T = [t_{ij}] = [r_{xx}(i-j)]$. This is the Yule–Walker system with $n = p$ and $E_p = 0$. When $\sigma_n \neq 0$, we have $\hat{T} = T + \sigma_n^2 I$ where $\hat{T}$ is the autocorrelation matrix for $\hat{x}(k)$. The value of σ_n^2 is the smallest eigenvalue of $\hat{T}$. Given knowledge of σ_n, T can be computed from $T = \hat{T} - \sigma_n^2 I$. The prediction coefficients can then be computed from the Yule–Walker equation $T\mathbf{a}_p = 0$. The zeros of the prediction error filter
$$z^p E_p(z) = z^p \left(1 - \sum_{j=1}^{p} a(j) z^{-j}\right)$$

all lie on the unit circle at $e^{i\omega_j}$ for $j = 1, 2, \ldots p$, giving the frequencies of the sinusoids.

4. [AGR87] The zeros of a polynomial are often sensitive to small errors in the coefficients. Computing such zeros accurately can be difficult. As an alternative the zeros of $z^p E_p(z)$ can be found as the eigenvalues of a unitary Hessenberg matrix. Let γ_j and δ_j be the Schur parameters and complementary parameters for the autocorrelation matrix R. Then $|\gamma_j| < 1$ for $1 \leq j \leq p-1$ and $|\gamma_p| = 1$. The matrix

$$H = G_1(\gamma_1) G_2(\gamma_2) \cdots G_p(\gamma_p)$$

with

$$G_j(\gamma_j) = I_{j-1} \oplus \begin{bmatrix} -\gamma_j & \delta_j \\ \delta_j & \overline{\gamma}_j \end{bmatrix} \oplus I_{p-j-1}$$

is unitary and upper Hessenberg. An explicit formula for the elements of H is

$$H = \begin{bmatrix} -\gamma_1 & -\delta_1\gamma_2 & -\delta_1\delta_2\gamma_3 & \cdots & -\delta_1 \cdots \delta_{p-1}\gamma_p \\ \delta_1 & -\overline{\gamma}_1\gamma_2 & -\overline{\gamma}_1\delta_2\gamma_3 & \cdots & -\overline{\gamma}_1\delta_2 \cdots \delta_{p-1}\gamma_p \\ & \delta_2 & -\overline{\gamma}_2\gamma_3 & & \vdots \\ & & \ddots & \ddots & \vdots \\ & & & \delta_{p-1} & -\overline{\gamma}_{p-1}\gamma_p \end{bmatrix}.$$

The eigenvalues of H are the zeros of $z^p E_p(z)$. The eigenvalues of a $p \times p$ unitary Hessenberg matrix can be found with $O(p^2)$ operations. An algorithm exploiting connections with Szegö polynomials was given in [Gra86] and stabilized in [Gra99]. A different, stable algorithm involving matrix pencils was given in [BE91].

Examples:

1. Consider a stationary random signal with known autocorrelations $r_{xx}(0) = 1$ and $r_{xx}(1) = a < 1$. The other autocorrelations are assumed to be unknown. The Yule–Walker system

$$\begin{bmatrix} 1 & a \\ a & 1 \end{bmatrix} \begin{bmatrix} 1 \\ -a_1(1) \end{bmatrix} = \begin{bmatrix} E_1 \\ 0 \end{bmatrix}$$

has solution $a_1(1) = a$ and $E_1 = 1 - a^2$. Thus, the maximum entropy estimate of the spectral density $S_x(e^{i\omega})$ is

$$S(e^{i\omega}) = \frac{1 - a^2}{|1 - ae^{-i\omega}|}.$$

77.7 Direction of Arrival Estimation

Definitions:

The **direction of arrival estimation** problem can be described as follows. We assume that n plane waves $s_j(k)$, $1 \leq j \leq n$ arrive at an array of m sensors from angles θ_j resulting in output $x_l(k)$, $1 \leq l \leq m$ from the sensors. We assume that the sensors lie in a plane and that it is necessary to estimate only a single angle of arrival for each signal. It is assumed that each sensor output is corrupted by noise $n_l(k)$, $1 \leq l \leq m$. The sensors experience different delays and attenuations of the signal $s_j(k)$ depending on their position and the direction of arrival. If the signals are **narrow-band signals**

$$s_j(k) = \operatorname{Re}\left(u_j(k)e^{i(\omega_0 k + v_j(k))}\right)$$

for slowly varying $u_j(k)$ and $v_j(k)$, then a signal delayed by l is approximately

$$s_j(k-l) = \operatorname{Re}\left(u_j(k-l)e^{i(\omega_0 k + v_j(k-l))}e^{-i\omega_0 l}\right) \approx \operatorname{Re}\left(u_j(k)e^{i(\omega_0 k + v_j(k))}e^{-i\omega_0 l}\right).$$

Thus, both delay and attenuation of the signals can be described by multiplication by a complex scalar dependent on θ_j. The observed signals are, therefore,

$$\mathbf{x}(k) = \sum_{j=1}^{n} \mathbf{a}(\theta_j)s_j(k) + \mathbf{n}(k),$$

where

$$\mathbf{x}(k) = \begin{bmatrix} x_1(k) \\ \vdots \\ x_m(k) \end{bmatrix}$$

and $\mathbf{a}(\theta)$ is the complex **array response vector**. In matrix notation the **signal model** is

$$\mathbf{x}(k) = A\mathbf{s}(k) + \mathbf{n}(k),$$

where

$$A = \begin{bmatrix} \mathbf{a}(\theta_1) & \mathbf{a}(\theta_2) & \cdots & \mathbf{a}(\theta_n) \end{bmatrix}.$$

The problem is to estimate the angles θ_j from a sequence $\mathbf{x}(k)$ of sensor output vectors. We assume that the components of the noise vector $\mathbf{n}(k)$ are uncorrelated, stationary, and zero mean. A more complete description of the problem is given in [RK89].

The **array manifold** is the set of all $\mathbf{a}(\theta)$ for θ in $[-\pi, \pi]$.

The **signal subspace** is the range space of the matrix A.

The **noise subspace** is the orthogonal complement of the signal subspace.

We define the spatial correlation matrices

$$R_{\mathbf{x}} = E[\mathbf{x}\mathbf{x}^*], \qquad R_{\mathbf{s}} = E[\mathbf{s}\mathbf{s}^*], \qquad \text{and} \qquad R_{\mathbf{n}} = E[\mathbf{n}\mathbf{n}^*]$$

where we assume R_s is positive definite. These definitions apply directly when dealing with stationary random signals. In the deterministic case they can be replaced with time averages.

Facts:

1. If the signal and noise are uncorrelated, then

$$R_{\mathbf{x}} = AR_{\mathbf{s}}A^* + R_{\mathbf{n}}.$$

2. The signal model implies that except for the effect of noise the observation vectors $\mathbf{x}(k)$ lie in the signal subspace. Thus, in the absence of noise, any n linearly independent observation vectors $\mathbf{x}(k)$ will give a basis for the signal subspace. The directions θ_j are determined by the signal subspace so long as the mapping from the set of angles θ_j to the signal subspace is invertible. We assume that the sensor array is designed to ensure invertibility.

3. The signal subspace can be estimated by solving a generalized eigenvalue problem. The n eigenvectors associated with the n largest generalized eigenvalues of the pencil

$$R_x - \lambda R_n$$

are the basis for the estimated signal subspace. This method can be used to obtain matrices X_s and X_n such that $X_s X_s^*$ is a projection for the signal subspace and $X_n X_n^*$ is a projection for the noise subspace.
4. [Sch79] In order to obtain the angles θ_j the **MUSIC algorithm** searches the array manifold to find angles that are close to the signal subspace in the sense that

$$M(\theta) = \frac{\mathbf{a}^*(\theta)\mathbf{a}(\theta)}{\mathbf{a}^*(\theta) X_n X_n^* \mathbf{a}(\theta)}$$

is large. The values of θ for which $M(\theta)$ has a peak are taken as the estimates of the angles θ_j, $1 \leq j \leq n$. The basic approach of the MUSIC algorithm can be used for a variety of parameter estimation problems, including the problem of finding sinusoids in noise.
5. [RK89] The *ESPRIT* algorithm imposes a structure on the array of sensors. It is assumed that the array is divided into two identical subarrays displaced along an $\mathbb{R}^2$ vector Δ. Let $x_j(k)$ be the output of sensor j in the first subarray and $y_j(k)$ be the output of the corresponding sensor in the second subarray. The displacement Δ causes a delay in the signal $x_j(k)$ relative to $y_j(k)$. If the signals arriving at the array are again narrow band signals centered at frequency ω_0, then the signal model is

$$\mathbf{x}(k) = \sum_{j=1}^{n} s_j(k)\mathbf{a}(\theta_j) + \mathbf{n}_x(k),$$

$$\mathbf{y}(k) = \sum_{j=1}^{n} s_j(k) e^{i\omega_0 \|\boldsymbol{\Delta}\|_2 \sin(\theta_j)/c} \mathbf{a}(\theta_j) + \mathbf{n}_y(k),$$

where θ_k is the angle of arrival relative to the subarray displacement vector. The combined ESPRIT signal model including both subarrays is

$$\begin{bmatrix} \mathbf{x}(k) \\ \mathbf{y}(k) \end{bmatrix} = \begin{bmatrix} A \\ A\Phi \end{bmatrix} \mathbf{s}(k) + \begin{bmatrix} \mathbf{n}_x(k) \\ \mathbf{n}_y(k) \end{bmatrix},$$

where the diagonal matrix $\Phi = \operatorname{diag}(e^{i\omega_0\|\boldsymbol{\Delta}\|_2 \sin(\theta_1)/c}, \ldots, e^{i\omega_0\|\boldsymbol{\Delta}\|_2 \sin(\theta_n)/c})$ characterizes the delay between the subarrays.
6. To compute the θ_j using the ESPRIT algorithm, we start with the signal subspace associated with the ESPRIT signal model estimated as before using a generalized eigenvalue problem. We assume that a $2m \times n$ matrix S with columns spanning the signal subspace

$$S = \begin{bmatrix} S_x \\ S_y \end{bmatrix}$$

has been computed and compute the $2n \times 2n$ matrix

$$V = \begin{bmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{bmatrix}$$

of right singular vectors of $\begin{bmatrix} S_x & S_y \end{bmatrix}$. Here, V_{11} and V_{22} are $n \times n$. The ESPRIT estimates of the values $e^{i\omega_0 \|\mathbf{\Delta}\|_2 \sin(\theta_k)/c}$ are the eigenvalues λ_j of $-V_{12}V_{22}^{-1}$ so that the estimate $\hat{\theta}_j$ of θ_j is

$$\hat{\theta}_j = \sin^{-1}(c \arg(\lambda_j)/(\|\mathbf{\Delta}\|_2 \omega_0))$$

for $j = 1, 2, \ldots, n$.

Examples:

1. We consider a single signal arriving at an array of two sensors with array response vector

$$\mathbf{a}(\theta) = \begin{bmatrix} e^{-i(\pi/2-\theta)} \\ 1 \end{bmatrix}.$$

If observations of the sensor outputs and solution of the generalized eigenvalue problem $R_x - \lambda R_n$ suggest that

$$X_s X_s^* = \begin{bmatrix} i/\sqrt{3} \\ 2/\sqrt{3} \end{bmatrix} \begin{bmatrix} -i/\sqrt{3} & 2/\sqrt{3} \end{bmatrix}$$

is the projection for the signal subspace, then the projection for the noise subspace is

$$X_n X_n^{\mathrm{T}} = \begin{bmatrix} -2i/\sqrt{3} \\ 1/\sqrt{3} \end{bmatrix} \begin{bmatrix} 2i/\sqrt{3} & 1/\sqrt{3} \end{bmatrix}.$$

In applying the MUSIC algorithm, we have

$$M(\theta) = \frac{2}{3|2e^{i\theta} + 1|^2}.$$

This function has a maximum of 2/3 at $\theta = \pi$. Thus, the MUSIC estimate of the angle from which the signal arrives is $\theta = \pi$.

Differential equations and differential-algebraic equations arise in numerous branches of science and engineering that include biology, chemistry, medicine, structural mechanics, and electrical engineering. This chapter is concerned with linear differential(-algebraic) equations with constant coefficients that can be analyzed completely via techniques from linear algebra. We discuss the existence and uniqueness of solutions of such equations as well as the stability theory.

78.1 Linear Differential Equations with Constant Coefficients: Basic Concepts

Definitions:

A **linear differential equation** in an unknown function $x : \mathbb{R} \to \mathbb{C}$, $t \mapsto x(t)$, has the form

$$\dot{x} = ax + f,$$

where $a \in \mathbb{C}$ and the inhomogeneity $f : \mathbb{R} \to \mathbb{C}$ is a given function. Here $\dot{x}$ denotes the derivative of $x(t)$ with respect to t.

A **linear differential equation of order** k for an unknown function $x : \mathbb{R} \to \mathbb{C}$ has the form

$$a_k x^{(k)} + \cdots + a_0 x = f,$$

where $a_0, \ldots, a_k \in \mathbb{C}$, $a_k \neq 0$ and $f : \mathbb{R} \to \mathbb{C}$. Here $x^{(k)}$ denotes the k-th derivative of $x(t)$ with respect to t.

A **system of linear differential(-algebraic) equations with constant coefficients** has the form

$$E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f},$$

where E, $A \in \mathbb{C}^{m\times n}$ are **coefficient matrices**, $\mathbf{x} : \mathbb{R} \to \mathbb{C}^n$ is a vector-valued function of unknowns, and the inhomogeneity $\mathbf{f} : \mathbb{R} \to \mathbb{C}^m$ is a given vector-valued function.

If $E = I_n$ and $A \in \mathbb{C}^{n\times n}$, then $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ is a system of **ordinary differential equations**; otherwise, it is a system of **differential-algebraic equations**.

A **homogeneous** system has $\mathbf{f}(t) \equiv 0$; otherwise, the system is **inhomogeneous**.

A **system of linear differential-algebraic equations of order** k for an unknown function $\mathbf{x} : \mathbb{R} \to \mathbb{C}^n$ has the form $A_k\mathbf{x}^{(k)} + \cdots + A_0\mathbf{x} = \mathbf{f}$, where $A_0, \ldots, A_k \in \mathbb{C}^{m\times n}$, $A_k \neq 0$ and $\mathbf{f} : \mathbb{R} \to \mathbb{C}^m$.

A continuously differentiable function $\mathbf{x} : \mathbb{R} \to \mathbb{C}^n$ is a **solution** of $E\dot{\mathbf{x}} = A\mathbf{x}+\mathbf{f}$ with a sufficiently often differentiable function $\mathbf{f}$ if it satisfies the equation pointwise.

A solution of $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ that also satisfies an initial condition $\mathbf{x}(t_0) = \mathbf{x}_0$ with $t_0 \in \mathbb{R}$ and $\mathbf{x}_0 \in \mathbb{C}^n$ is a solution of the **initial value problem**.

If the initial value problem $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$, $\mathbf{x}(t_0) = \mathbf{x}_0$ has a solution, then the initial condition is called **consistent**.

Facts:

1. [Cam80, p. 33] Let $E, A \in \mathbb{C}^{n\times n}$. If E is nonsingular, then the system $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ is equivalent to the system of ordinary differential equations $\dot{\mathbf{x}} = E^{-1}A\mathbf{x} + E^{-1}\mathbf{f}$.
2. [Arn92, p. 105] The k-th order system of differential-algebraic equations

$$A_k\mathbf{y}^{(k)} + \cdots + A_0\mathbf{y} = \mathbf{g}$$

can be rewritten as a first-order system $E\dot{\mathbf{x}} = A\mathbf{x}+\mathbf{f}$, where $\mathbf{f} = [\,0,\,\ldots,\,0,\,\mathbf{g}^T\,]^T$ and

$$E = \begin{bmatrix} I & & & \\ & \ddots & & \\ & & I & \\ & & & A_k \end{bmatrix}, \quad A = \begin{bmatrix} 0 & I & & 0 \\ \vdots & \ddots & \ddots & \\ 0 & \cdots & 0 & I \\ -A_0 & \cdots & -A_{k-2} & -A_{k-1} \end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix} \mathbf{y} \\ \vdots \\ \mathbf{y}^{(k-2)} \\ \mathbf{y}^{(k-1)} \end{bmatrix}.$$

Applications:

1. Consider a mass–spring–damper model as shown in Figure 78.1. This model is described by the equation

$$m\ddot{x} + d\dot{x} + kx = 0,$$

where m is a mass, k is a spring constant, and d is a damping parameter. Since $m \neq 0$, we obtain the following first-order system of ordinary differential equations:

$$\begin{bmatrix} \dot{x} \\ \dot{v} \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -k/m & -d/m \end{bmatrix} \begin{bmatrix} x \\ v \end{bmatrix},$$

where the velocity is denoted by v.

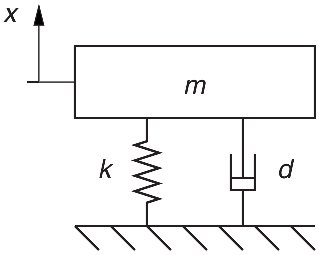

FIGURE 78.1 A mass–spring–damper model.

2. Consider a one-dimensional heat equation

$$\frac{\partial}{\partial t}T(t,\xi) = c\frac{\partial^2}{\partial \xi^2}T(t,\xi), \quad (t,\xi) \in (0,t_e) \times (0,l),$$

together with an initial condition $T(0,\xi) = g(\xi)$ and Cauchy boundary conditions

$$\alpha_1 T(t,0) + \alpha_2 \frac{\partial}{\partial n}T(t,0) = u(t),$$
$$\beta_1 T(t,l) + \beta_2 \frac{\partial}{\partial n}T(t,l) = v(t).$$

Here $T(t,\xi)$ is the temperature field in a thin beam of length l, $c > 0$ is the heat conductivity of the material, $g(\xi)$, $u(t)$, and $v(t)$ are given functions, and $\frac{\partial}{\partial n}$ denotes the derivative in the direction of the outward normal. A spatial discretization by a finite difference method with $n+1$ equidistant grid points leads to the initial value problem $\dot{\mathbf{x}} = A_{a,b}\mathbf{x} + \mathbf{f}$, $\mathbf{x}(0) = \mathbf{x}_0$, where

$$\mathbf{x}(t) = [\,T(t,h),\ T(t,2h),\ \ldots,\ T(t,nh)\,]^T, \quad \mathbf{x}_0 = [\,g(h),\ g(2h),\ \ldots,\ g(nh)\,]^T,$$
$$\mathbf{f}(t) = [cu(t)/(h^2\alpha_1 - h\alpha_2),\ 0,\ \ldots,\ 0,\ cv(t)/(h^2\beta_1 + h\beta_2)\,]^T,$$

and

$$A_{a,b} = \frac{c}{h^2}\begin{bmatrix} -a & 1 & & & \\ 1 & -2 & 1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & -2 & 1 \\ & & & 1 & -b \end{bmatrix} \in \mathbb{R}^{n\times n}$$

with $h = l/(n+1)$, $a = (2h\alpha_1 - \alpha_2)/(h\alpha_1 - \alpha_2)$, and $b = (2h\beta_1 + \beta_2)/(h\beta_1 + \beta_2)$.

3. A simple pendulum as shown in Figure 78.2 describes the movement of a mass point with mass m and Cartesian coordinates (x,y) under the influence of gravity in a distance l around

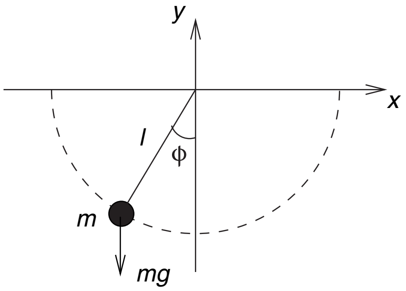

FIGURE 78.2 A simple pendulum.

the origin. The equations of motion have the form

$$\begin{aligned} m\ddot{x} + 2x\lambda &= 0, \\ m\ddot{y} + 2y\lambda + mg &= 0, \\ x^2 + y^2 - l^2 &= 0, \end{aligned}$$

where λ is a Lagrange multiplier. Transformation of this system into the first-order form by introducing new variables $v = \dot{x}$ and $w = \dot{y}$ and linearization at the equilibrium $x_e = 0$, $y_e = -l$, $v_e = 0$, $w_e = 0$, and $\lambda_e = mg/(2l)$ yields the homogeneous first-order linear differential-algebraic system

$$\begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & m & 0 & 0 \\ 0 & 0 & 0 & m & 0 \\ 0 & 0 & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \dot{\widetilde{x}} \\ \dot{\widetilde{y}} \\ \dot{\widetilde{v}} \\ \dot{\widetilde{w}} \\ \dot{\widetilde{\lambda}} \end{bmatrix} = \begin{bmatrix} 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ -2\lambda_e & 0 & 0 & 0 & 0 \\ 0 & -2\lambda_e & 0 & 0 & 2l \\ 0 & -2l & 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \widetilde{x} \\ \widetilde{y} \\ \widetilde{v} \\ \widetilde{w} \\ \widetilde{\lambda} \end{bmatrix},$$

where $\widetilde{x} = x - x_e$, $\widetilde{y} = y - y_e$, $\widetilde{v} = v - v_e$, $\widetilde{w} = w - w_e$, and $\widetilde{\lambda} = \lambda - \lambda_e$.

The motion of the pendulum can also be described by the ordinary differential equation

$$\ddot{\varphi} = -\omega^2 \sin(\varphi),$$

where φ is an angle between the vertical axis and the pendulum and $\omega = \sqrt{g/l}$ is an angular frequency of the motion. By introducing a new variable $\psi = \dot{\varphi}$ and linearization at the equilibrium $\varphi_e = 0$ and $\psi_e = 0$, we obtain the first-order homogeneous system

$$\begin{bmatrix} \dot{\widetilde{\varphi}} \\ \dot{\widetilde{\psi}} \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -\omega^2 & 0 \end{bmatrix} \begin{bmatrix} \widetilde{\varphi} \\ \widetilde{\psi} \end{bmatrix}.$$

4. Consider a simple RLC electrical circuit as shown in Figure 78.3. Using Kirchhoff's and Ohm's laws, the circuit can be described by the system $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ with

$$E = \begin{bmatrix} L & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}, \quad A = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1/C & 0 & 0 & 0 \\ -R & 0 & 0 & 1 \\ 0 & 1 & 1 & 1 \end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix} i \\ v_L \\ v_C \\ v_R \end{bmatrix}, \quad \mathbf{f} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ -v \end{bmatrix}.$$

Here R, L, and C are the resistance, inductance, and capacitance, respectively; v_R, v_L, and v_C are the corresponding voltage drops, i is the current, and v is the voltage source. From the last two equations in the system, we find $v_R = Ri$ and $v_L = v - v_C - Ri$. Substituting

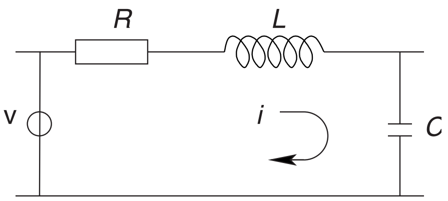

FIGURE 78.3 A simple RLC circuit.

v_L in the first equation and introducing a new variable $w_C = i/C$, we obtain the system of ordinary differential equations

$$\begin{bmatrix} \dot{v}_C \\ \dot{w}_C \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1/(LC) & -R/L \end{bmatrix} \begin{bmatrix} v_C \\ w_C \end{bmatrix} + \begin{bmatrix} 0 \\ v/(LC) \end{bmatrix}.$$

This shows the relationship to the mass–spring–damper model as in Application 1.

78.2 Linear Ordinary Differential Equations

Facts:

The following facts can be found in [Gan59a, pp. 116–124, 153–154].

1. Let $J_A = T^{-1}AT$ be in Jordan canonical form. Then $e^{At} = Te^{J_A t}T^{-1}$. (See Chapter 6 and Chapter 17 for more information on the Jordan canonical form and the matrix exponential.)
2. Every solution of the homogeneous system $\dot{\mathbf{x}} = A\mathbf{x}$ has the form $\mathbf{x}(t) = e^{At}\mathbf{v}$ with $\mathbf{v} \in \mathbb{C}^n$.
3. The initial value problem $\dot{\mathbf{x}} = A\mathbf{x}$, $\mathbf{x}(t_0) = \mathbf{x}_0$ has the unique solution $\mathbf{x}(t) = e^{A(t-t_0)}\mathbf{x}_0$.
4. The initial value problem $\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$, $\mathbf{x}(t_0) = \mathbf{x}_0$ has a unique solution for every initial vector $\mathbf{x}_0$ and every continuous inhomogeneity $\mathbf{f}$. This solution is given by

$$\mathbf{x}(t) = e^{A(t-t_0)}\mathbf{x}_0 + \int_{t_0}^{t} e^{A(t-\tau)}\mathbf{f}(\tau)\, d\tau.$$

Examples:

1. Let

$$A = \begin{bmatrix} 3 & 3 & 1 \\ 0 & 0 & 0 \\ -1 & -1 & 1 \end{bmatrix}, \qquad \mathbf{x}_0 = \begin{bmatrix} 1 \\ 2 \\ 3 \end{bmatrix}, \qquad \mathbf{f}(t) = \begin{bmatrix} -3t^2 - 3t \\ 2t \\ t^2 + t - 1 \end{bmatrix}.$$

For

$$T = \begin{bmatrix} 1 & 0 & -1 \\ 0 & 0 & 1 \\ -1 & 1 & 0 \end{bmatrix} \quad \text{and} \quad T^{-1} = \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 0 \end{bmatrix},$$

we have

$$J_A = T^{-1}AT = \left[\begin{array}{cc|c} 2 & 1 & 0 \\ 0 & 2 & 0 \\ \hline 0 & 0 & 0 \end{array}\right].$$

Then

$$\begin{aligned} e^{At} &= \begin{bmatrix} 1 & 0 & -1 \\ 0 & 0 & 1 \\ -1 & 1 & 0 \end{bmatrix} \left[\begin{array}{cc|c} e^{2t} & te^{2t} & 0 \\ 0 & e^{2t} & 0 \\ \hline 0 & 0 & 1 \end{array}\right] \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 & 1 \\ 0 & 1 & 0 \end{bmatrix} \\ &= \begin{bmatrix} (1+t)e^{2t} & (1+t)e^{2t} - 1 & te^{2t} \\ 0 & 1 & 0 \\ -te^{2t} & -te^{2t} & (1-t)e^{2t} \end{bmatrix}. \end{aligned}$$

Every solution of the homogeneous system $\dot{\mathbf{x}} = A\mathbf{x}$ has the form

$$\mathbf{x}(t) = e^{At}\mathbf{v} = \begin{bmatrix} ((1+t)v_1 + (1+t)v_2 + tv_3)e^{2t} - v_2 \\ v_2 \\ (-tv_1 - tv_2 + (1-t)v_3)e^{2t} \end{bmatrix}$$

with $\mathbf{v} = [v_1,\, v_2,\, v_3]^T$. The solution of the initial value problem $\dot{\mathbf{x}} = A\mathbf{x}$, $\mathbf{x}(0) = \mathbf{x}_0$ has the form

$$\mathbf{x}(t) = e^{At}\mathbf{x}_0 = \begin{bmatrix} (3+6t)e^{2t} - 2 \\ 2 \\ (3-6t)e^{2t} \end{bmatrix}.$$

The initial value problem $\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$, $\mathbf{x}(0) = \mathbf{x}_0$ has the solution

$$\mathbf{x}(t) = \begin{bmatrix} (3+6t)e^{2t} + t - 2 \\ t^2 + 2 \\ (3-6t)e^{2t} + 1 \end{bmatrix}.$$

Applications:

1. Consider the matrix A from the mass–spring–damper example

$$A = \begin{bmatrix} 0 & 1 \\ -k/m & -d/m \end{bmatrix}.$$

The Jordan canonical form of A is given by $J_A = T^{-1}AT = \operatorname{diag}(\lambda_1, \lambda_2)$, where

$$T = \begin{bmatrix} 1 & 1 \\ \lambda_1 & \lambda_2 \end{bmatrix}, \qquad T^{-1} = \frac{1}{\lambda_2 - \lambda_1}\begin{bmatrix} \lambda_2 & -1 \\ -\lambda_1 & 1 \end{bmatrix}$$

and

$$\lambda_1 = \frac{-d - \sqrt{d^2 - 4km}}{2m}, \qquad \lambda_2 = \frac{-d + \sqrt{d^2 - 4km}}{2m}$$

are the eigenvalues of A. We have

$$e^{At} = T\operatorname{diag}(e^{\lambda_1 t}, e^{\lambda_2 t})T^{-1} = \frac{1}{\lambda_2 - \lambda_1}\begin{bmatrix} \lambda_2 e^{\lambda_1 t} - \lambda_1 e^{\lambda_2 t} & e^{\lambda_2 t} - e^{\lambda_1 t} \\ \lambda_1\lambda_2(e^{\lambda_1 t} - e^{\lambda_2 t}) & \lambda_2 e^{\lambda_2 t} - \lambda_1 e^{\lambda_1 t} \end{bmatrix}.$$

The solution of the mass–spring–damper model with the initial conditions $x(0) = x_0$ and $v(0) = 0$ is given by

$$x(t) = \frac{x_0}{\lambda_2 - \lambda_1}\left(\lambda_2 e^{\lambda_1 t} - \lambda_1 e^{\lambda_2 t}\right), \qquad v(t) = \frac{\lambda_1\lambda_2 x_0}{\lambda_2 - \lambda_1}\left(e^{\lambda_1 t} - e^{\lambda_2 t}\right).$$

2. Since the matrix $A_{a,b}$ in the semidiscretized heat equation is symmetric, there exists an orthogonal matrix U such that $U^T A_{a,b} U = \operatorname{diag}(\lambda_1, \ldots, \lambda_n)$, where $\lambda_1, \ldots, \lambda_n \in \mathbb{R}$ are the eigenvalues of $A_{a,b}$. (See Section 8.2 and Chapter 55.) In this case, $e^{A_{a,b}t} = U\operatorname{diag}(e^{\lambda_1 t}, \ldots, e^{\lambda_n t})U^T$.

78.3 Linear Differential-Algebraic Equations

Definitions:

A **Drazin inverse** A^D of a matrix $A \in \mathbb{C}^{n\times n}$ is defined as the unique solution of the system of matrix equations

$$A^D A A^D = A^D, \qquad A A^D = A^D A, \qquad A^{k+1} A^D = A^k,$$

where k is a smallest nonnegative integer such that $\operatorname{rank}(A^{k+1}) = \operatorname{rank}(A^k)$. See Chapter 27 for more information about generalized inverses.

Let $E, A \in \mathbb{C}^{m\times n}$. A pencil of the form

$$\lambda E - A = \operatorname{diag}\left(\mathcal{L}_{n_1}, \ldots, \mathcal{L}_{n_p}, \mathcal{M}_{m_1}, \ldots, \mathcal{M}_{m_q}, \mathcal{J}_k, \mathcal{N}_s\right)$$

is called pencil in **Kronecker canonical form** if the block entries have the following properties: every entry $\mathcal{L}_{n_j} = \lambda L_{n_j} - R_{n_j}$ is a bidiagonal block of size $n_j \times (n_j+1)$, $n_j \in \mathbb{N}$, where

$$L_{n_j} = \begin{bmatrix} 1 & 0 & & \\ & \ddots & \ddots & \\ & & 1 & 0 \end{bmatrix}, \qquad R_{n_j} = \begin{bmatrix} 0 & 1 & & \\ & \ddots & \ddots & \\ & & 0 & 1 \end{bmatrix};$$

every entry $\mathcal{M}_{m_j} = \lambda L_{m_j}^T - R_{m_j}^T$ is a bidiagonal block of size $(m_j+1) \times m_j$, $m_j \in \mathbb{N}$; the entry $\mathcal{J}_k = \lambda I_k - A_k$ is a block of size $k \times k$, $k \in \mathbb{N}$, where A_k is in Jordan canonical form; the entry $\mathcal{N}_s = \lambda N_s - I_s$ is a block of size $s \times s$, $s \in \mathbb{N}$, where $N_s = \operatorname{diag}(N_{s_1}, \ldots, N_{s_r})$; and

$$N_{s_j} = \begin{bmatrix} 0 & 1 & & \\ & \ddots & \ddots & \\ & & \ddots & 1 \\ & & & 0 \end{bmatrix}$$

is a nilpotent Jordan block with index of nilpotency s_j.

The numbers $n_1, \ldots, n_p$ are called the **right Kronecker indices** of the pencil $\lambda E - A$.

The numbers $m_1, \ldots, m_q$ are called the **left Kronecker indices** of the pencil $\lambda E - A$.

The number $\nu = \max_{1\le j\le r} s_j$ is called the **index** of the pencil $\lambda E - A$.

A matrix pencil $\lambda E - A$ with $E, A \in \mathbb{C}^{m\times n}$ is called **regular**, if $m = n$ and $\det(\lambda E - A) \neq 0$ for some $\lambda \in \mathbb{C}$. Otherwise, the pencil is called **singular**.

Let E, $A \in \mathbb{C}^{m,n}$. Subspaces $W_l \subset \mathbb{C}^m$ and $W_r \subset \mathbb{C}^n$ are called **left** and **right reducing subspaces** of the pencil $\lambda E - A$ if $W_l = EW_r + AW_r$ and $\dim(W_l) = \dim(W_r) - p$, where p is the number of $\mathcal{L}_{n_j}$ blocks in the Kronecker canonical form.

Let $\lambda E - A$ be a regular pencil. Subspaces W_l, $W_r \subset \mathbb{C}^n$ are called **left** and **right deflating subspaces** of $\lambda E - A$ if $W_l = EW_r + AW_r$ and $\dim(W_l) = \dim(W_r)$.

Let W_1, $W_2 \subset \mathbb{C}^n$ be subspaces such that $W_1 \cap W_2 = \{\mathbf{0}\}$ and $W_1 + W_2 = \mathbb{C}^n$. A matrix $P \in \mathbb{C}^{n,n}$ is called a **projector** onto W_1 along W_2 if $P^2 = P$, $\operatorname{range}(P) = W_1$, and $\ker(P) = W_2$.

Let $\lambda E - A$ be a regular pencil. If $T_l, T_r \in \mathbb{C}^{n\times n}$ are nonsingular matrices such that $T_l^{-1}(\lambda E - A)T_r$ is in Kronecker canonical form, then

$$P_l = T_l \begin{bmatrix} I_k & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} T_l^{-1}, \qquad P_r = T_r \begin{bmatrix} I_k & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} T_r^{-1}$$

are the **spectral projectors** onto the left and right deflating subspaces of $\lambda E - A$ corresponding to the finite eigenvalues along the left and right deflating subspaces corresponding to the eigenvalue at infinity.

Facts:

1. [Cam80, p. 8] If $A \in \mathbb{C}^{n\times n}$ is nonsingular, then $A^D = A^{-1}$.
2. [Cam80, p. 8] Let
$$J_A = T^{-1}AT = \begin{bmatrix} A_1 & \mathbf{0} \\ \mathbf{0} & A_0 \end{bmatrix}$$
be in Jordan canonical form, where A_1 contains all the Jordan blocks associated with the nonzero eigenvalues, and A_0 contains all the Jordan blocks associated with the eigenvalue 0. Then
$$A^D = T \begin{bmatrix} A_1^{-1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} T^{-1}.$$
3. [Gan59b, pp. 29–37] For every matrix pencil $\lambda E - A$ with $E,\ A \in \mathbb{C}^{m\times n}$ there exist nonsingular matrices $T_l \in \mathbb{C}^{m\times m}$ and $T_r \in \mathbb{C}^{n\times n}$ such that $T_l^{-1}(\lambda E - A)T_r$ is in Kronecker canonical form. The Kronecker canonical form is unique up to permutation of the diagonal blocks, i.e., the kind, size, and number of the blocks are characteristic for the pencil $\lambda E - A$. (For more information on matrix pencils, see Section 56.1.)
4. [Gan59b, p. 47] If $\mathbf{f}(t) = [f_1(t), \ldots, f_{n_j}(t)]^T$ is an n_j-times continuously differentiable vector-valued function and $g(t)$ is an arbitrary (n_j+1)-times continuously differentiable function, then the system $L_{n_j}\dot{\mathbf{x}} = R_{n_j}\mathbf{x} + \mathbf{f}$ has a continuously differentiable solution of the form
$$\mathbf{x}(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \\ \vdots \\ x_{n_j+1}(t) \end{bmatrix} = \begin{bmatrix} g(t) \\ g^{(1)}(t) - f_1(t) \\ \vdots \\ g^{(n_j)}(t) - \sum_{i=1}^{n_j} f_i^{(n_j-i)}(t) \end{bmatrix}.$$
A consistent initial condition has to satisfy this defining equation at t_0.
5. [Gan59b, p. 47] A system of differential-algebraic equations $L_{m_j}^T\dot{\mathbf{x}} = R_{m_j}^T\mathbf{x} + \mathbf{f}$ with a vector-valued function $\mathbf{f}(t) = [f_1(t), \ldots, f_{m_j+1}(t)]^T$ has a unique solution if and only if $\mathbf{f}$ is m_j-times continuously differentiable and $\sum_{i=1}^{m_j+1} f_i^{(i-1)}(t) \equiv 0$. If this holds, then the solution is given by
$$\mathbf{x}(t) = \begin{bmatrix} x_1(t) \\ \vdots \\ x_{m_j}(t) \end{bmatrix} = \begin{bmatrix} -\sum_{i=1}^{m_j} f_{i+1}^{(i-1)}(t) \\ \vdots \\ -f_{m_j+1}(t) \end{bmatrix}.$$
A consistent initial condition has to satisfy this defining equation at t_0.
6. [Gan59b, p. 48] A system $N_{s_j}\dot{\mathbf{x}} = \mathbf{x} + \mathbf{f}$ has a unique continuously differentiable solution $\mathbf{x}$ if $\mathbf{f}$ is s_j-times continuously differentiable. This solution is given by
$$\mathbf{x}(t) = -\sum_{i=0}^{s_j-1} N_{s_j}^i \mathbf{f}^{(i)}(t).$$
A consistent initial condition has to satisfy this defining equation at t_0.

7. [Cam80, pp. 37–39] If the pencil $\lambda E - A$ is regular of index ν, then for every ν-times differentiable inhomogeneity $\mathbf{f}$ there exists a solution of the differential-algebraic system $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$. Every solution of this system has the form
$$\mathbf{x}(t) = e^{\hat{E}^D\hat{A}(t-t_0)}\hat{E}^D\hat{E}\mathbf{v} + \int_{t_0}^{t} e^{\hat{E}^D\hat{A}(t-\tau)}\hat{E}^D\hat{\mathbf{f}}(\tau)\,d\tau - (I - \hat{E}^D\hat{E})\sum_{j=0}^{\nu-1}(\hat{E}\hat{A}^D)^j\hat{A}^D\hat{\mathbf{f}}^{(j)}(t),$$
where $\mathbf{v} \in \mathbb{C}^n$, $\hat{E} = (\lambda_0 E - A)^{-1}E$, $\hat{A} = (\lambda_0 E - A)^{-1}A$, and $\hat{\mathbf{f}} = (\lambda_0 E - A)^{-1}\mathbf{f}$ for some $\lambda_0 \in \mathbb{C}$ such that $\lambda_0 E - A$ is nonsingular.
8. [Cam80, pp. 37–39] If the pencil $\lambda E - A$ is regular of index ν and if $\mathbf{f}$ is ν-times differentiable, then the initial value problem $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$, $\mathbf{x}(t_0) = \mathbf{x}_0$ possesses a solution if and only if there exists $\mathbf{v} \in \mathbb{C}^n$ that satisfies
$$\mathbf{x}_0 = \hat{E}^D\hat{E}\mathbf{v} - (I - \hat{E}^D\hat{E})\sum_{j=0}^{\nu-1}(\hat{E}\hat{A}^D)^j\hat{A}^D\hat{\mathbf{f}}^{(j)}(t_0).$$
If such a $\mathbf{v}$ exists, then the solution is unique.
9. [KM06, p. 21] The existence of a unique solution of $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$, $\mathbf{x}(t_0) = \mathbf{x}_0$ does not imply that the pencil $\lambda E - A$ is regular.
10. [Cam80, pp. 41–44] If the pencil $\lambda E - A$ is singular, then the initial value problem $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$, $\mathbf{x}(t_0) = \mathbf{x}_0$ may have no solutions or the solution, if it exists, may not be unique.
11. [Sty02, pp. 23–26] Let the pencil $\lambda E - A$ be regular of index ν. If
$$T_l^{-1}(\lambda E - A)T_r = \begin{bmatrix} \lambda I - A_k & \mathbf{0} \\ \mathbf{0} & \lambda N_s - I \end{bmatrix}$$
is in Kronecker canonical form, then the solution of $E\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$, $\mathbf{x}(t_0) = \mathbf{x}_0$ can be represented as
$$\mathbf{x}(t) = \mathcal{F}(t - t_0)E\mathbf{x}_0 + \int_{t_0}^{t}\mathcal{F}(t-\tau)\mathbf{f}(\tau)\,d\tau + \sum_{j=0}^{\nu-1}F_{-j-1}\mathbf{f}^{(j)}(t),$$
where
$$\mathcal{F}(t) = T_r\begin{bmatrix} e^{A_k t} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}T_l^{-1}, \qquad F_{-j} = T_r\begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & -N_s^{j-1} \end{bmatrix}T_l^{-1}.$$

Examples:

1. The system
$$\begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}\dot{\mathbf{x}} = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}\mathbf{x} + \begin{bmatrix} 0 \\ g(t) \end{bmatrix}, \qquad \mathbf{x}(0) = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$$
has no solution if $g(t) \not\equiv 0$. For $g(t) \equiv 0$, this system has the solution $\mathbf{x}(t) = [\,e^t,\ \phi(t)\,]^T$, where $\phi(t)$ is a differentiable function such that $\phi(0) = 0$.
2. The system
$$\begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix}\dot{\mathbf{x}} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}\mathbf{x} + \begin{bmatrix} -\sin(t) \\ -\cos(t) \\ 0 \end{bmatrix}, \quad \mathbf{x}(0) = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$$
has a unique solution $\mathbf{x}(t) = [\,\cos(t),\ 0\,]^T$, but the pencil $\lambda E - A$ is singular.

Applications:

1. The pencil in the linearized pendulum example has the Kronecker canonical form
$$\operatorname{diag}(\mathcal{J}_2,\mathcal{N}_3)=\lambda\left[\begin{array}{cc|ccc}1&0&0&0&0\\0&1&0&0&0\\\hline 0&0&0&1&0\\0&0&0&0&1\\0&0&0&0&0\end{array}\right]-\left[\begin{array}{cc|ccc}-i\sqrt{g/l}&0&0&0&0\\0&i\sqrt{g/l}&0&0&0\\\hline 0&0&1&0&0\\0&0&0&1&0\\0&0&0&0&1\end{array}\right].$$
This pencil is regular of index 3. Since the linearized pendulum system is homogeneous, it has a unique solution for every consistent initial condition.
2. The pencil of the circuit equation has the Kronecker canonical form
$$\operatorname{diag}(\mathcal{J}_2,\mathcal{N}_2)=\lambda\left[\begin{array}{cc|cc}1&0&0&0\\0&1&0&0\\\hline 0&0&0&0\\0&0&0&0\end{array}\right]-\left[\begin{array}{cc|cc}\lambda_1&0&0&0\\0&\lambda_2&0&0\\\hline 0&0&1&0\\0&0&0&1\end{array}\right],$$
with
$$\lambda_1=-\frac{R}{2L}-\sqrt{\frac{R^2}{4L^2}-\frac{1}{LC}},\qquad \lambda_2=-\frac{R}{2L}+\sqrt{\frac{R^2}{4L^2}-\frac{1}{LC}}.$$
This pencil is regular of index 1. Hence, there exists a unique continuous solution for every continuous voltage source $v(t)$ and for every consistent initial condition.

78.4 Stability of Linear Ordinary Differential Equations

The notion of stability is used to study the behavior of dynamical systems under initial perturbations around equilibrium points. In this section, we consider the stability of linear homogeneous ordinary differential equations with constant coefficients only. For extensions of this concept to general nonlinear systems, see, e.g., [Ces63] and [Hah67].

Definitions:

The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $\dot{\mathbf{x}}=A\mathbf{x}$ is called **stable in the sense of Lyapunov**, or simply **stable**, if for every $\varepsilon>0$ there exists a $\delta=\delta(\varepsilon)>0$ such that any solution $\mathbf{x}$ of $\dot{\mathbf{x}}=A\mathbf{x}$, $\mathbf{x}(t_0)=\mathbf{x}_0$ with $\|\mathbf{x}_0\|_2<\delta$ satisfies $\|\mathbf{x}(t)\|_2<\varepsilon$ for all $t\geq t_0$.

The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $\dot{\mathbf{x}}=A\mathbf{x}$ is called **asymptotically stable** if it is stable and $\lim_{t\to\infty}\mathbf{x}(t)=0$ for any solution $\mathbf{x}$ of $\dot{\mathbf{x}}=A\mathbf{x}$.

The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $\dot{\mathbf{x}}=A\mathbf{x}$ is called **unstable** if it is not stable.

The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $\dot{\mathbf{x}}=A\mathbf{x}$ is called **exponentially stable** if there exist $\alpha>0$ and $\beta>0$ such that the solution $\mathbf{x}$ of $\dot{\mathbf{x}}=A\mathbf{x}$, $\mathbf{x}(t_0)=\mathbf{x}_0$ satisfies $\|\mathbf{x}(t)\|_2\leq\alpha\, e^{-\beta(t-t_0)}\|\mathbf{x}_0\|_2$ for all $t\geq t_0$.

Facts:

1. [Gan59a, pp. 125–129] The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $\dot{\mathbf{x}}=A\mathbf{x}$ is stable if and only if all the eigenvalues of A have nonpositive real part and those with zero real part have the same algebraic and geometric multiplicities. If at least one of these conditions is violated, then the equilibrium $\mathbf{x}_e(t)\equiv 0$ of $\dot{\mathbf{x}}=A\mathbf{x}$ is unstable.
2. [Gan59a, pp. 125–129] The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $\dot{\mathbf{x}}=A\mathbf{x}$ is asymptotically stable if and only if all the eigenvalues of A have negative real part.

3. [Ces63, p. 22] Let $p_A(\lambda) = \det(\lambda I - A) = \lambda^n + a_1\lambda^{n-1} + \cdots + a_n$ be the characteristic polynomial of $A \in \mathbb{R}^{n\times n}$. If the equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable, then $a_j > 0$ for $j = 1, \ldots, n$.
4. [Gan59b, pp. 185–189] The equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable if and only if the Lyapunov equation $A^*X + XA = -Q$ has a unique Hermitian, positive definite solution X for every Hermitian, positive definite matrix Q.
5. [God97] Let H be a Hermitian, positive definite solution of the Lyapunov equation
$$A^*H + HA = -I$$
and let $\mathbf{x}$ be a solution of the initial value problem $\dot{\mathbf{x}} = A\mathbf{x}$, $\mathbf{x}(0) = \mathbf{x}_0$. Then in terms of the original data,
$$\|\mathbf{x}(t)\|_2 \leq \sqrt{\kappa(A)}\, e^{-t\|A\|_2/\kappa(A)}\|\mathbf{x}_0\|_2,$$
where $\kappa(A) = 2\|A\|_2\|H\|_2$.
6. [Hah67, pp. 113–117] The equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $\dot{\mathbf{x}} = A\mathbf{x}$ is exponentially stable if and only if it is asymptotically stable.
7. [Hah67, p. 16] If the equilibrium $\mathbf{x}_e(t) \equiv 0$ of the homogeneous system $\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable, then all the solutions of the inhomogeneous system $\dot{\mathbf{x}} = A\mathbf{x} + \mathbf{f}$ with a bounded inhomogeneity $\mathbf{f}$ are bounded.

Examples:

1. Consider the linear system $\dot{\mathbf{x}} = A\mathbf{x}$ with
$$A = \begin{bmatrix} -1 & 0 \\ 0 & 2 \end{bmatrix}.$$
For the initial condition $\mathbf{x}(0) = [1,\ 0]^T$, this system has the solution $\mathbf{x}(t) = [e^{-t},\ 0]^T$ that is bounded for all $t \geq 0$. However, this does not mean that the equilibrium $\mathbf{x}_e(t) \equiv 0$ is stable. For linear systems with constant coefficients, stability means that the solution $\mathbf{x}(t)$ remains bounded for all time and for all initial conditions, but not just for some specific initial condition. If we can find at least one initial condition that causes one of the states to approach infinity with time, then the equilibrium is unstable. For the above system, we can choose, for example, $\mathbf{x}(0) = [1,\ 1]^T$. In this case $\mathbf{x}(t) = [e^{-t},\ e^{2t}]^T$ is unbounded, which proves that the equilibrium $\mathbf{x}_e(t) \equiv 0$ is unstable.
2. Consider the linear system $\dot{\mathbf{x}} = A\mathbf{x}$ with
$$A = \begin{bmatrix} -0.1 & -1 \\ 1 & -0.1 \end{bmatrix}.$$
The eigenvalues of A are $-0.1 \pm i$, and, hence, the equilibrium $\mathbf{x}_e(t) \equiv 0$ is asymptotically stable. Indeed, the solution of this system is given by $\mathbf{x}(t) = e^{At}\mathbf{x}(0)$, which can be written in the real form as
$$x_1(t) = e^{-0.1t}(x_1(0)\cos(t) - x_2(0)\sin(t)),$$
$$x_2(t) = e^{-0.1t}(x_1(0)\sin(t) + x_2(0)\cos(t)).$$
(See also Chapter 79.) Thus, for all initial conditions $x_1(0)$ and $x_2(0)$, the solution tends to zero as $t \to \infty$. The phase portrait for $x_1(0) = 1$ and $x_2(0) = 0$ is presented in Figure 78.4.
3. Consider the linear system $\dot{\mathbf{x}} = A\mathbf{x}$ with
$$A = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}.$$

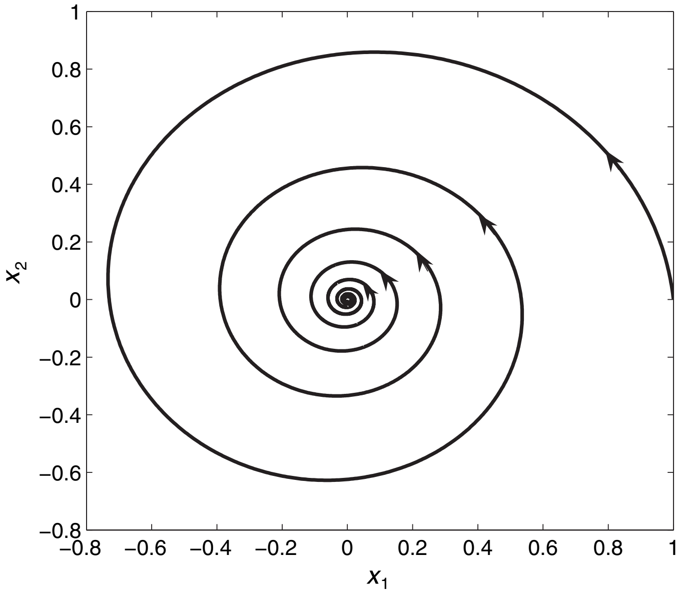

FIGURE 78.4 Asymptotic stability.

The matrix A has the eigenvalues $\pm i$. The solution of this system $\mathbf{x}(t) = e^{At}\mathbf{x}(0)$ can be written in the real form as

$$x_1(t) = x_1(0)\cos(t) - x_2(0)\sin(t),$$
$$x_2(t) = x_1(0)\sin(t) + x_2(0)\cos(t).$$

It remains bounded for all initial values $x_1(0)$ and $x_2(0)$, and, hence, the equilibrium $\mathbf{x}_e(t) \equiv 0$ is stable. The phase portrait for $x_1(0) = 1$ and $x_2(0) = 0$ is given in Figure 78.5.

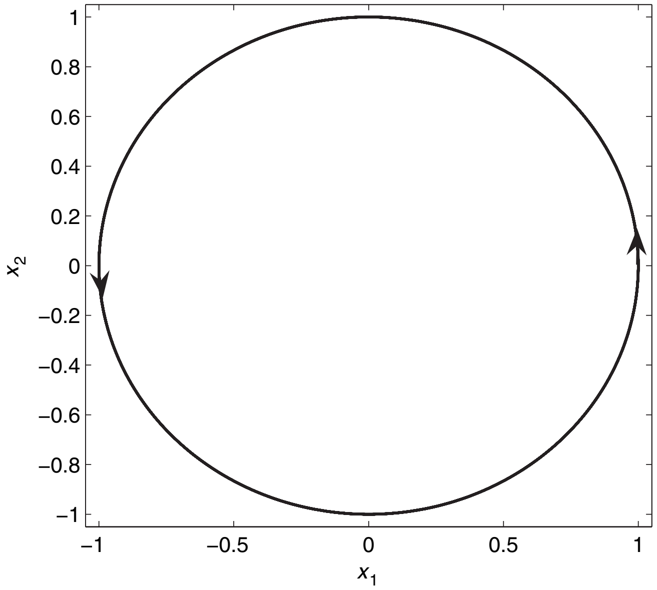

FIGURE 78.5 Stability.

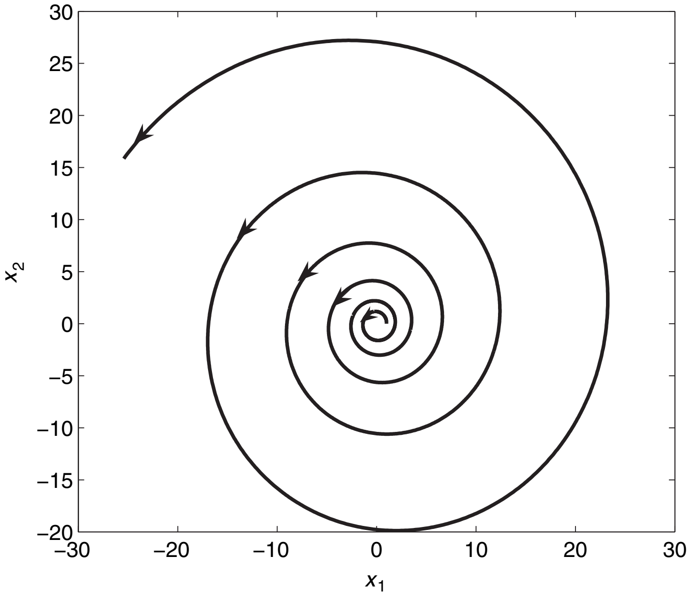

FIGURE 78.6 Instability.

4. Consider the linear system $\dot{\mathbf{x}} = A\mathbf{x}$ with

$$A = \begin{bmatrix} 0.1 & -1 \\ 1 & 0.1 \end{bmatrix}.$$

The eigenvalues of A are $0.1 \pm i$. The solution of this system in the real form is given by

$$x_1(t) = e^{0.1t}(x_1(0)\cos(t) - x_2(0)\sin(t)),$$
$$x_2(t) = e^{0.1t}(x_1(0)\sin(t) + x_2(0)\cos(t)).$$

It is unbounded for all nontrivial initial conditions. Thus, the equilibrium $\mathbf{x}_e(t) \equiv 0$ is unstable. The phase portrait of the solution with $x_1(0) = 1$ and $x_2(0) = 0$ is shown in Figure 78.6.

5. Consider the linear system $\dot{\mathbf{x}} = A\mathbf{x}$ with

$$A = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \in \mathbb{R}^{2\times 2}.$$

The characteristic polynomial of the matrix A is given by $p_A(\lambda) = \lambda^2 - (a+d)\lambda + (ad - bc)$ and the eigenvalues of A have the form

$$\lambda_1 = \frac{a+d}{2} + \frac{\sqrt{(a+d)^2 - 4(ad-bc)}}{2}, \qquad \lambda_2 = \frac{a+d}{2} - \frac{\sqrt{(a+d)^2 - 4(ad-bc)}}{2}.$$

We have the following cases:

$a+d<0,$	$ad-bc>0$	$\mathrm{Re}(\lambda_1)<0$, $\mathrm{Re}(\lambda_2)<0$,	Asymptotically stable
$a+d<0,$	$ad-bc=0$	$\lambda_1=0$, $\lambda_2<0$	Stable
$a+d<0,$	$ad-bc<0$	$\lambda_1>0$, $\lambda_2<0$	Unstable
$a+d=0,$	$ad-bc>0$	$\lambda_1=i\alpha$, $\lambda_2=-i\alpha$, α - real	Stable
$a+d=0,$ $a^2+b^2+c^2+d^2\neq 0$	$ad-bc=0$	$\lambda_1=0$, $\lambda_2=0$	Unstable
$a=0,\ b=0,\ c=0,\ d=0$		$\lambda_1=0$, $\lambda_2=0$	Stable
$a+d=0,$	$ad-bc<0$	$\lambda_1>0$, $\lambda_2<0$	Unstable
$a+d>0,$	$ad-bc\leq 0$	$\lambda_1>0$, $\lambda_2\leq 0$	Unstable
$a+d>0,$	$ad-bc>0$	$\mathrm{Re}(\lambda_1)>0$, $\mathrm{Re}(\lambda_2)>0$	Unstable

Applications:

1. Consider the semidiscretized heat equation; see Application 78.1.2. Let $\alpha_1=\beta_1=1$ and $\alpha_2=\beta_2=0$. Then $a=b=2$ and the matrix $A_{2,2}$ has the eigenvalues
$$\lambda_j(A_{2,2})=-\frac{4c}{h^2}\sin^2\frac{j\pi}{2(n+1)}.$$
In this case, the equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $\dot{\mathbf{x}}=A_{2,2}\mathbf{x}$ is asymptotically stable. However, for $\alpha_1=\beta_1=0$ and $\alpha_2=\beta_2=1$, we have $a=b=1$. Then the matrix $A_{1,1}$ has a simple zero eigenvalue and, hence, the equilibrium $\mathbf{x}_e(t)\equiv 0$ of $\dot{\mathbf{x}}=A_{1,1}\mathbf{x}$ is only stable.
2. Consider the mass–spring–damper model with $m>0$, $d\geq 0$, and $k\geq 0$. The coefficient matrix of this model has eigenvalues
$$\lambda_1=\frac{-d-\sqrt{d^2-4km}}{2m},\qquad \lambda_2=\frac{-d+\sqrt{d^2-4km}}{2m}.$$
For $d=0$, the equilibrium $\mathbf{x}_e(t)\equiv 0$ is unstable if $k=0$, and it is stable if $k>0$. For $d>0$, the equilibrium $\mathbf{x}_e(t)\equiv 0$ is stable if $k=0$, and it is asymptotically stable if $k>0$.

78.5 Stability of Linear Differential-Algebraic Equations

Definitions:

The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $E\dot{\mathbf{x}}=A\mathbf{x}$ is called **stable in the sense of Lyapunov**, or simply **stable**, if for every $\varepsilon>0$ there exists a $\delta=\delta(\varepsilon)>0$ such that any solution $\mathbf{x}$ of $E\dot{\mathbf{x}}=A\mathbf{x}$, $\mathbf{x}(t_0)=P_r\mathbf{x}_0$ with $\|P_r\mathbf{x}_0\|_2<\delta$ satisfies $\|\mathbf{x}(t)\|_2<\varepsilon$ for all $t\geq t_0$.

The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $E\dot{\mathbf{x}}=A\mathbf{x}$ is called **asymptotically stable** if it is stable and $\lim\limits_{t\to\infty}\mathbf{x}(t)=0$ for every solution $\mathbf{x}$ of $E\dot{\mathbf{x}}=A\mathbf{x}$.

The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $E\dot{\mathbf{x}}=A\mathbf{x}$ is called **unstable** if it is not stable.

The equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $E\dot{\mathbf{x}}=A\mathbf{x}$ is called **exponentially stable** if there exist constants $\alpha>0$ and $\beta>0$ such that the solution $\mathbf{x}$ of $E\dot{\mathbf{x}}=A\mathbf{x}$, $\mathbf{x}(t_0)=P_r\mathbf{x}_0$ satisfies $\|\mathbf{x}(t)\|_2\leq\alpha\, e^{-\beta(t-t_0)}\|P_r\mathbf{x}_0\|_2$ for all $t\geq t_0$.

Facts:

1. [Dai89, pp. 68–69] If the pencil $\lambda E-A$ is regular, then the equilibrium $\mathbf{x}_e(t)\equiv 0$ of the system $E\dot{\mathbf{x}}=A\mathbf{x}$ is stable if and only if all finite eigenvalues of the pencil $\lambda E-A$ have nonpositive real part and those with zero real part have the same algebraic and geometric multiplicities.

2. [Dai89, pp. 68–69] If the pencil $\lambda E - A$ is regular, then the equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $E\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable if and only if all finite eigenvalues of $\lambda E - A$ have negative real part.
3. [Sty02, p. 48] Let Q be a Hermitian matrix such that $\mathbf{v}^* Q \mathbf{v} > 0$ for all nonzero vectors $\mathbf{v} \in \text{range}(P_r)$. The equilibrium $\mathbf{x}_e(t) \equiv 0$ of $E\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable if the generalized Lyapunov equation $E^*XA + A^*XE = -Q$ has a Hermitian, positive semidefinite solution X.
4. [Sty02, pp. 49–52] The equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $E\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable and the pencil $\lambda E - A$ is of index at most one if and only if the generalized Lyapunov equation $E^*XA + A^*XE = -E^*QE$, with Hermitian, positive definite Q has a Hermitian, positive semidefinite solution X.
5. [TMK95] The equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $E\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable and the pencil $\lambda E - A$ is of index at most one if and only if the generalized Lyapunov equation
$$A^*X + Y^*A = -Q, \qquad Y^*E = E^*X,$$
with Hermitian, positive definite Q has a solution (X, Y) such that E^*X is Hermitian, positive semidefinite.
6. [Sty02, pp. 52–54] The equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $E\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable if and only if the projected generalized Lyapunov equation
$$E^*XA + A^*XE = -P_r^* Q P_r, \qquad X = P_l^* X P_l$$
has a unique Hermitian, positive semidefinite solution X for every Hermitian, positive definite matrix Q.
7. [Sty02] The equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $E\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable if and only if the projected generalized Lyapunov equation
$$EYA^* + AYE^* = -P_l Q P_l^*, \qquad Y = P_r Y P_r^*$$
has a unique Hermitian, positive semidefinite solution Y for every Hermitian, positive definite matrix Q.
8. [Sty02, pp. 28–31] Let H be a symmetric, positive semidefinite solution of the projected generalized Lyapunov equation $E^*HA + A^*HE = -P_r^*P_r$, $H = P_l^*HP_l$ and let $\mathbf{x}$ be a solution of the initial value problem $E\dot{\mathbf{x}} = A\mathbf{x}$, $\mathbf{x}(0) = P_r\mathbf{x}_0$. Then in terms of the original data,
$$\|\mathbf{x}(t)\|_2 \leq \sqrt{\kappa(E,A)\|E\|_2\|(EP_r + A(I - P_r))^{-1}\|_2}\, e^{-t\|A\|_2/(\kappa(E,A)\|E\|_2)}\|P_r\mathbf{x}_0\|_2,$$
where $\kappa(E, A) = 2\|E\|_2\|A\|_2\|H\|_2$.
9. From the previous fact it follows that the equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $E\dot{\mathbf{x}} = A\mathbf{x}$ is exponentially stable if and only if it is asymptotically stable.

Examples:

1. The generalized Lyapunov equation $E^*XA + A^*XE = -Q$ with
$$E = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}, \qquad A = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}, \qquad Q = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$
has no solution, although the finite eigenvalue of $\lambda E - A$ is negative and $\lambda E - A$ has index one.

2. The generalized Lyapunov equation $E^*XA + A^*XE = -E^*QE$ with

$$E = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \qquad A = \begin{bmatrix} -2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \qquad Q = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 2 & 0 \\ 0 & 0 & 2 \end{bmatrix}$$

   has no Hermitian, positive semidefinite solution, although the finite eigenvalue of $\lambda E - A$ is negative.
3. The generalized Lyapunov equation $A^*X + Y^*A = -Q$, $Y^*E = E^*X$ with

$$E = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \qquad A = \begin{bmatrix} -1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \qquad Q = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

   has no solution, although the finite eigenvalue of $\lambda E - A$ is negative.

Applications:

1. The finite eigenvalues of the pencil $\lambda E - A$ in the RLC electrical circuit example are given by

$$\lambda_1 = -\frac{R}{2L} - \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}}, \qquad \lambda_2 = -\frac{R}{2L} + \sqrt{\frac{R^2}{4L^2} - \frac{1}{LC}}.$$

   Hence, the equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $E\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable.
2. The pencil $\lambda E - A$ in the linearized pendulum example has the finite eigenvalues $\lambda_1 = -i\sqrt{g/l}$ and $\lambda_2 = i\sqrt{g/l}$. In this case the equilibrium $\mathbf{x}_e(t) \equiv 0$ of the system $E\dot{\mathbf{x}} = A\mathbf{x}$ is stable but not asymptotically stable.

Linear algebra plays a key role in the theory of dynamical systems, and concepts from dynamical systems allow the study, characterization, and generalization of many objects in linear algebra, such as similarity of matrices, eigenvalues, and (generalized) eigenspaces. The most basic form of this interplay can be seen as a matrix A gives rise to a continuous time dynamical system via the linear ordinary differential equation $\dot{\mathbf{x}} = A\mathbf{x}$, or a discrete time dynamical system via iteration $\mathbf{x}_{n+1} = A\mathbf{x}_n$. The properties of the solutions are intimately related to the properties of the matrix A. Matrices also define nonlinear systems on smooth manifolds, such as the sphere $\mathbb{S}^{d-1}$ in $\mathbb{R}^d$, the Grassmann manifolds, or on classical (matrix) Lie groups. Again, the behavior of such systems is closely related to matrices and their properties. And the behavior of nonlinear systems, e.g., of differential equations $\dot{\mathbf{y}} = f(\mathbf{y})$ in $\mathbb{R}^d$ with a fixed point $\mathbf{y}_0 \in \mathbb{R}^d$, can be described locally around $\mathbf{y}_0$ via the linear differential equation $\dot{\mathbf{x}} = D_{\mathbf{y}} f(\mathbf{y}_0)\mathbf{x}$.

Since A. M. Lyapunov's thesis in 1892, it has been an intriguing problem how to construct an appropriate linear algebra for time varying systems. Note that, e.g., for stability of the solutions of $\dot{\mathbf{x}} = A(t)\mathbf{x}$, it is not sufficient that for all $t \in \mathbb{R}$ the matrices $A(t)$ have only eigenvalues with negative real part (see [Hah67], Chapter 74). Of course, Floquet theory (see [Flo83]) gives an elegant solution for the periodic case, but it is not immediately clear how to build a linear algebra around Lyapunov's "order numbers" (now called Lyapunov exponents). The multiplicative ergodic theorem of Oseledets [Ose68] resolves the issue for measurable linear systems with stationary time dependencies, and the Morse spectrum together with Selgrade's theorem [Sel75] clarifies the situation for continuous linear systems with chain transitive time dependencies.

This chapter provides a first introduction to the interplay between linear algebra and analysis/topology in continuous time. Section 79.1 recalls facts about d-dimensional linear differential equations $\dot{\mathbf{x}} = A\mathbf{x}$, emphasizing eigenvalues and (generalized) eigenspaces. Section 79.2 studies solutions in Euclidian space $\mathbb{R}^d$ from the point of view of topological equivalence and conjugacy with related characterizations of the matrix A. Section 79.3 presents, in a fairly general set-up, the concepts of chain recurrence and Morse decompositions for dynamical systems. These ideas are then applied in Section 79.4 to nonlinear systems on Grassmannian and flag manifolds induced by a single matrix A, with emphasis on characterizations of the matrix A from this point of view. Section 79.5 introduces linear skew product flows as a way to model time varying linear systems $\dot{\mathbf{x}} = A(t)\mathbf{x}$ with, e.g., periodic, measurable ergodic, and continuous chain transitive time dependencies. Sections 79.6, 79.7, and 79.8 develop generalizations of (real parts of) eigenvalues and eigenspaces as a starting point for a linear algebra for classes of time varying linear systems, namely periodic, random, and robust systems. (For the corresponding generalization of the imaginary parts of eigenvalues see, e.g., [Arn98] for the measurable ergodic case and [CFJ07] for the continuous, chain transitive case.) Section 79.9 introduces some basic ideas to study genuinely nonlinear systems via linearization, emphasizing invariant manifolds and Grobman–Hartman-type results that compare nonlinear behavior locally to the behavior of associated linear systems.

Notation:

In this chapter, the set of $d \times d$ real matrices is denoted by $gl(d, \mathbb{R})$ rather than $\mathbb{R}^{d\times d}$.

79.1 Linear Differential Equations

Linear differential equations can be solved explicitly if one knows the eigenvalues and a basis of eigenvectors (and generalized eigenvectors, if necessary). The key idea is that of the Jordan form of a matrix. The real parts of the eigenvectors determine the exponential behavior of the solutions, described by the Lyapunov exponents and the corresponding Lyapunov subspaces.

For information on matrix functions, including the matrix exponential, see Chapter 17. For information on the Jordan canonical form, see Chapter 6. Systems of first order linear differential equations are also discussed in Chapter 78.

Definitions:

For a matrix $A \in gl(d, \mathbb{R})$, the **exponential** $e^A \in \mathrm{GL}(d, \mathbb{R})$ is defined by $e^A = I + \sum_{n=1}^{\infty} \frac{1}{n!} A^n \in GL(d, \mathbb{R})$, where $I \in gl(d, \mathbb{R})$ is the identity matrix (cf. Section 17.2).

A **linear differential equation** (with constant coefficients) is given by a matrix $A \in gl(d, \mathbb{R})$ via $\dot{\mathbf{x}}(t) = A\mathbf{x}(t)$, where $\dot{\mathbf{x}}$ denotes differentiation with respect to t. Any function $\mathbf{x} : \mathbb{R} \longrightarrow \mathbb{R}^d$ such that $\dot{\mathbf{x}}(t) = A\mathbf{x}(t)$ for all $t \in \mathbb{R}$ is called a solution of $\dot{\mathbf{x}} = A\mathbf{x}$.

The **initial value problem** for a linear differential equation $\dot{\mathbf{x}} = A\mathbf{x}$ consists in finding, for a given **initial value** $\mathbf{x}_0 \in \mathbb{R}^d$, a solution $\mathbf{x}(\cdot, \mathbf{x}_0)$ that satisfies $\mathbf{x}(0, \mathbf{x}_0) = \mathbf{x}_0$.

The distinct (complex) eigenvalues of $A \in gl(d, \mathbb{R})$ will be denoted $\mu_1, \dots, \mu_r$. (For definitions and more information about eigenvalues, eigenvectors, and eigenspaces, see Section 4.4. For information about generalized eigenspaces, see Chapter 6.) The real version of the generalized eigenspace is denoted by $E(A, \mu_k) \subset \mathbb{R}^d$ or simply E_k for $k = 1, \dots, r \leq d$.

The **real Jordan form** of a matrix $A \in gl(d, \mathbb{R})$ is denoted by $J_A^{\mathbb{R}}$. Note that for any matrix A there is a matrix $T \in GL(d, \mathbb{R})$ such that $A = T^{-1} J_A^{\mathbb{R}} T$.

Let $\mathbf{x}(\cdot, \mathbf{x}_0)$ be a solution of the linear differential equation $\dot{\mathbf{x}} = A\mathbf{x}$. Its **Lyapunov exponent** for $\mathbf{x}_0 \neq 0$ is defined as $\lambda(\mathbf{x}_0) = \limsup_{t\to\infty} \frac{1}{t} \log \|\mathbf{x}(t, \mathbf{x}_0)\|$, where log denotes the natural logarithm and $\| \cdot \|$ is any norm in $\mathbb{R}^d$.

Let $\mu_k = \lambda_k + i\nu_k$, $k = 1, \ldots, r$, be the distinct eigenvalues of $A \in gl(d, \mathbb{R})$. We order the distinct real parts of the eigenvalues as $\lambda_1 < \ldots < \lambda_l$, $1 \leq l \leq r \leq d$, and define the **Lyapunov space** of λ_j as $L(\lambda_j) = \bigoplus E_k$, where the direct sum is taken over all generalized real eigenspaces associated to eigenvalues with real part equal to λ_j. Note that $\bigoplus_{j=1}^{l} L(\lambda_j) = \mathbb{R}^d$.

The **stable, center, and unstable subspaces** associated with the matrix $A \in gl(d, \mathbb{R})$ are defined as $L^- = \bigoplus\{L(\lambda_j),\ \lambda_j < 0\}$, $L^0 = \bigoplus\{L(\lambda_j),\ \lambda_j = 0\}$, and $L^+ = \bigoplus\{L(\lambda_j),\ \lambda_j > 0\}$, respectively.

The zero solution $\mathbf{x}(t, 0) \equiv 0$ is called **exponentially stable** if there exists a neighborhood $U(0)$ and positive constants $a, b > 0$ such that $\mathbf{x}(t, \mathbf{x}_0) \leq a\|\mathbf{x}_0\|e^{-bt}$ for all $t \in \mathbb{R}$ and $\mathbf{x}_0 \in U(0)$.

Facts:

Literature: [Ama90], [HSD04].

1. For each $A \in gl(d, \mathbb{R})$ the solutions of $\dot{\mathbf{x}} = A\mathbf{x}$ form a d-dimensional vector space $sol(A) \subset C^\infty(\mathbb{R}, \mathbb{R}^d)$ over $\mathbb{R}$, where $C^\infty(\mathbb{R}, \mathbb{R}^d) = \{f : \mathbb{R} \longrightarrow \mathbb{R}^d,\ f \text{ is infinitely often differentiable}\}$. Note that the solutions of $\dot{\mathbf{x}} = A\mathbf{x}$ are even real analytic.
2. For each initial value problem given by $A \in gl(d, \mathbb{R})$ and $\mathbf{x}_0 \in \mathbb{R}^d$, the solution $\mathbf{x}(\cdot, \mathbf{x}_0)$ is unique and given by $\mathbf{x}(t, \mathbf{x}_0) = e^{At}\mathbf{x}_0$.
3. Let $\mathbf{v}_1, \ldots, \mathbf{v}_d \in \mathbb{R}^d$ be a basis of $\mathbb{R}^d$. Then the functions $\mathbf{x}(\cdot, \mathbf{v}_1), \ldots, \mathbf{x}(\cdot, \mathbf{v}_d)$ form a basis of the solution space $sol(A)$. The matrix function $X(\cdot) := [\mathbf{x}(\cdot, \mathbf{v}_1), \ldots, \mathbf{x}(\cdot, \mathbf{v}_d)]$ is called a fundamental matrix of $\dot{\mathbf{x}} = A\mathbf{x}$, and it satisfies $\dot{X}(t) = AX(t)$.
4. Let $A \in gl(d, \mathbb{R})$ with distinct eigenvalues $\mu_1, \ldots, \mu_r \in \mathbb{C}$ and corresponding multiplicities $n_k = \alpha(\mu_k)$, $k = 1, \ldots, r$. If E_k are the corresponding generalized real eigenspaces, then $\dim E_k = n_k$ and $\bigoplus_{k=1}^{r} E_k = \mathbb{R}^d$, i.e., every matrix has a set of generalized real eigenvectors that form a basis of $\mathbb{R}^d$.
5. If $A = T^{-1}J_A^{\mathbb{R}}T$, then $e^{At} = T^{-1}e^{J_A^{\mathbb{R}}t}T$, i.e., for the computation of exponentials of matrices it is sufficient to know the exponentials of Jordan form matrices.
6. Let $\mathbf{v}_1, \ldots, \mathbf{v}_d$ be a basis of generalized real eigenvectors of A. If $\mathbf{x}_0 = \sum_{i=1}^{d} \alpha_i\, \mathbf{v}_i$, then $\mathbf{x}(t, \mathbf{x}_0) = \sum_{i=1}^{d} \alpha_i \mathbf{x}(t, \mathbf{v}_i)$ for all $t \in \mathbb{R}$. This reduces the computation of solutions to $\dot{\mathbf{x}} = A\mathbf{x}$ to the computation of solutions for Jordan blocks; see the examples below or [HSD04, Chap. 5] for a discussion of this topic.
7. Each generalized real eigenspace E_k is invariant for the linear differential equation $\dot{\mathbf{x}} = A\mathbf{x}$, i.e., for $\mathbf{x}_0 \in E_k$ it holds that $\mathbf{x}(t, \mathbf{x}_0) \in E_k$ for all $t \in \mathbb{R}$.
8. The Lyapunov exponent $\lambda(\mathbf{x}_0)$ of a solution $\mathbf{x}(\cdot, \mathbf{x}_0)$ (with $\mathbf{x}_0 \neq 0$) satisfies $\lambda(\mathbf{x}_0) = \lim_{t\to\pm\infty} \frac{1}{t} \log \|\mathbf{x}(t, \mathbf{x}_0)\| = \lambda_j$ if and only if $\mathbf{x}_0 \in L(\lambda_j)$. Hence, associated to a matrix $A \in gl(d, \mathbb{R})$ are exactly l Lyapunov exponents, the distinct real parts of the eigenvalues of A.
9. The following are equivalent:
   (a) The zero solution $\mathbf{x}(t, 0) \equiv 0$ of the differential equation $\dot{\mathbf{x}} = A\mathbf{x}$ is asymptotically stable.
   (b) The zero solution is exponentially stable.
   (c) All Lyapunov exponents are negative.
   (d) $L^- = \mathbb{R}^d$.

Examples:

1. Let $A = \text{diag}(a_1, \ldots, a_d)$ be a diagonal matrix. Then the solution of the linear differential equation $\dot{\mathbf{x}} = A\mathbf{x}$ with initial value $\mathbf{x}_0 \in \mathbb{R}^d$ is given by

$$\mathbf{x}(t, \mathbf{x}_0) = e^{At}\mathbf{x}_0 = \begin{bmatrix} e^{a_1 t} & & & \\ & \cdot & & \\ & & \cdot & \\ & & & \cdot \\ & & & & e^{a_d t} \end{bmatrix} \mathbf{x}_0.$$

2. Let $\mathbf{e}_1 = [1, 0, \ldots, 0]^T, \ldots, \mathbf{e}_d = [0, 0, \ldots, 1]^T$ be the standard basis of $\mathbb{R}^d$. Then $\{\mathbf{x}(\cdot, \mathbf{e}_1), \ldots, \mathbf{x}(\cdot, \mathbf{e}_d)\}$ is a basis of the solution space $sol(A)$.
3. Let $A = \operatorname{diag}(a_1, \ldots, a_d)$ be a diagonal matrix. Then the standard basis $\{\mathbf{e}_1, \ldots, \mathbf{e}_d\}$ of $\mathbb{R}^d$ consists of eigenvectors of A.
4. Let $A \in gl(d, \mathbb{R})$ be diagonalizable, i.e., there exists a transformation matrix $T \in GL(d, \mathbb{R})$ and a diagonal matrix $D \in gl(d, \mathbb{R})$ with $A = T^{-1}DT$. Then the solution of the linear differential equation $\dot{\mathbf{x}} = A\mathbf{x}$ with initial value $x_0 \in \mathbb{R}^d$ is given by $\mathbf{x}(t, \mathbf{x}_0) = T^{-1}e^{Dt}T\mathbf{x}_0$, where e^{Dt} is given in Example 1.
5. Let $B = \begin{bmatrix} \lambda & -\nu \\ \nu & \lambda \end{bmatrix}$ be the real Jordan block associated with a complex eigenvalue $\mu = \lambda + i\nu$ of the matrix $A \in gl(d, \mathbb{R})$. Let $\mathbf{y}_0 \in E(A, \mu)$, the real eigenspace of μ. Then the solution $\mathbf{y}(t, \mathbf{y}_0)$ of $\dot{\mathbf{y}} = B\mathbf{y}$ is given by $\mathbf{y}(t, \mathbf{y}_0) = e^{\lambda t} \begin{bmatrix} \cos \nu t & -\sin \nu t \\ \sin \nu t & \cos \nu t \end{bmatrix} \mathbf{y}_0$. According to Fact 6 this is also the $E(A, \mu)$-component of the solutions of $\dot{\mathbf{x}} = J_A^{\mathbb{R}}\mathbf{x}$.
6. Let B be a Jordan block of dimension n associated with the real eigenvalue μ of a matrix $A \in gl(d, \mathbb{R})$. Then for

$$B = \begin{bmatrix} \mu & 1 & & & \\ & \cdot & \cdot & & \\ & & \cdot & \cdot & \\ & & & \cdot & \cdot \\ & & & \cdot & 1 \\ & & & & \mu \end{bmatrix} \quad \text{one has } e^{Bt} = e^{\mu t} \begin{bmatrix} 1 & t & \frac{t^2}{2!} & \cdot & \cdot & \frac{t^{n-1}}{(n-1)!} \\ & \cdot & \cdot & \cdot & & \cdot \\ & & \cdot & \cdot & \cdot & \cdot \\ & & & \cdot & \cdot & \frac{t^2}{2!} \\ & & & & \cdot & t \\ & & & & & 1 \end{bmatrix}.$$

In other words, for $\mathbf{y}_0 = [y_1, \ldots, y_n]^T \in E(A, \mu)$, the jth component of the solution of $\dot{\mathbf{y}} = B\mathbf{y}$ reads $y_j(t, \mathbf{y}_0) = e^{\mu t} \sum_{k=j}^{n} \frac{t^{k-j}}{(k-j)!} y_k$. According to Fact 6 this is also the $E(A, \mu)$-component of $e^{J_A^{\mathbb{R}} t}$.
7. Let B be a real Jordan block of dimension $n = 2m$ associated with the complex eigenvalue $\mu = \lambda + i\nu$ of a matrix $A \in gl(d, \mathbb{R})$. Then with $D = \begin{bmatrix} \lambda & -\nu \\ \nu & \lambda \end{bmatrix}$ and $I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$, for

$$B = \begin{bmatrix} D & I & & & \\ & \cdot & \cdot & & \\ & & \cdot & \cdot & \\ & & & \cdot & \cdot \\ & & & \cdot & I \\ & & & & D \end{bmatrix} \quad \text{one has } e^{Bt} = e^{\lambda t} \begin{bmatrix} \widehat{D} & t\widehat{D} & \frac{t^2}{2!}\widehat{D} & \cdot & \cdot & \frac{t^{n-1}}{(n-1)!}\widehat{D} \\ & \cdot & \cdot & \cdot & & \cdot \\ & & \cdot & \cdot & \cdot & \cdot \\ & & & \cdot & \cdot & \frac{t^2}{2!}\widehat{D} \\ & & & & \cdot & t\widehat{D} \\ & & & & & \widehat{D} \end{bmatrix},$$

where $\widehat{D} = \begin{bmatrix} \cos \nu t & -\sin \nu t \\ \sin \nu t & \cos \nu t \end{bmatrix}$. In other words, for $\mathbf{y}_0 = [y_1, z_1, \ldots, y_m, z_m]^T \in E(A, \mu)$, the jth components, $j = 1, \ldots, m$, of the solution of $\dot{\mathbf{y}} = B\mathbf{y}$ read

$$y_j(t, \mathbf{y}_0) = e^{\mu t} \sum_{k=j}^{m} \tfrac{t^{k-j}}{(k-j)!}(y_k \cos \nu t - z_k \sin \nu t),$$

$$z_j(t, \mathbf{y}_0) = e^{\mu t} \sum_{k=j}^{m} \tfrac{t^{k-j}}{(k-j)!}(z_k \cos \nu t + y_k \sin \nu t).$$

According to Fact 6, this is also the $E(A, \mu)$-component of $e^{J_A^{\mathbb{R}} t}$.

8. Using these examples and Facts 5 and 6, it is possible to compute explicitly the solutions to any linear differential equation in $\mathbb{R}^d$.
9. Recall that for any matrix A there is a matrix $T \in GL(d, \mathbb{R})$ such that $A = T^{-1} J_A^{\mathbb{R}} T$, where $J_A^{\mathbb{R}}$ is the real Jordan canonical form of A. The exponential behavior of the solutions of $\dot{\mathbf{x}} = A\mathbf{x}$ can be read off from the diagonal elements of $J_A^{\mathbb{R}}$.

79.2 Linear Dynamical Systems in $\mathbb{R}^d$

The solutions of a linear differential equation $\dot{\mathbf{x}} = A\mathbf{x}$, where $A \in gl(d, \mathbb{R})$, define a (continuous time) dynamical system, or linear flow in $\mathbb{R}^d$. The standard concepts for comparison of dynamical systems are equivalences and conjugacies that map trajectories into trajectories. For linear flows in $\mathbb{R}^d$ these concepts lead to two different classifications of matrices, depending on the smoothness of the conjugacy or equivalence.

Definitions:

The real square matrix A is **hyperbolic** if it has no eigenvalues on the imaginary axis.

A **continuous dynamical system** over the "time set" $\mathbb{R}$ with state space M, a complete metric space, is defined as a map $\Phi : \mathbb{R} \times M \longrightarrow M$ with the properties

(i) $\Phi(0, x) = x$ for all $x \in M$,
(ii) $\Phi(s + t, x) = \Phi(s, \Phi(t, x))$ for all $s, t \in \mathbb{R}$ and all $x \in M$,
(iii) Φ is continuous (in both variables).

The map Φ is also called a (continuous) flow.

For each $x \in M$ the set $\{\Phi(t, x), t \in \mathbb{R}\}$ is called the **orbit (or trajectory)** of the system through x.

For each $t \in \mathbb{R}$ the **time-t map** is defined as $\varphi_t = \Phi(t, \cdot) : M \longrightarrow M$. Using time-$t$ maps, the properties (i) and (ii) above can be restated as (i)$'$ $\varphi_0 = id$, the identity map on M, (ii)$'$ $\varphi_{s+t} = \varphi_s \circ \varphi_t$ for all $s, t \in \mathbb{R}$.

A **fixed point (or equilibrium)** of a dynamical system Φ is a point $x \in M$ with the property $\Phi(t, x) = x$ for all $t \in \mathbb{R}$.

An orbit $\{\Phi(t, x), t \in \mathbb{R}\}$ of a dynamical system Φ is called **periodic** if there exists $\widehat{t} \in \mathbb{R}$, $\widehat{t} > 0$ such that $\Phi(\widehat{t} + s, x) = \Phi(s, x)$ for all $s \in \mathbb{R}$. The infimum of the positive $\widehat{t} \in \mathbb{R}$ with this property is called the **period** of the orbit. Note that an orbit of period 0 is a fixed point.

Denote by $C^k(X, Y)$ $(k \geq 0)$ the set of k-times **differentiable functions** between C^k-manifolds X and Y, with C^0 denoting continuous.

Let Φ, $\Psi : \mathbb{R} \times M \longrightarrow M$ be two continuous dynamical systems of class C^k $(k \geq 0)$, i.e., for $k \geq 1$ the state space M is at least a C^k-manifold and Φ, Ψ are C^k-maps. The flows Φ and Ψ are:

(i) C^k**−equivalent** $(k \geq 1)$ if there exists a (local) C^k-diffeomorphism $h : M \to M$ such that h takes orbits of Φ onto orbits of Ψ, **preserving the orientation** (but not necessarily parametrization by time), i.e.,
  (a) For each $x \in M$ there is a strictly increasing and continuous parametrization map $\tau_x : \mathbb{R} \to \mathbb{R}$ such that $h(\Phi(t, x)) = \Psi(\tau_x(t), h(x))$ or, equivalently,

(b) For all $x \in M$ and $\delta > 0$ there exists $\varepsilon > 0$ such that for all $t \in (0, \delta)$, $h(\Phi(t, x)) = \Psi(t', h(x))$ for some $t' \in (0, \varepsilon)$.

(ii) C^k-**conjugate** ($k \geq 1$) if there exists a (local) C^k-diffeomorphism $h : M \to M$ such that $h(\Phi(t, x)) = \Psi(t, h(x))$ for all $x \in M$ and $t \in \mathbb{R}$.

Similarly, the flows Φ and Ψ are C^0-**equivalent** if there exists a (local) homeomorphism $h : M \to M$ satisfying the properties of (i) above, and they are C^0-**conjugate** if there exist a (local) homeomorphism $h : M \to M$ satisfying the properties of (ii) above. Often, C^0-equivalence is called **topological equivalence,** and C^0-conjugacy is called **topological conjugacy** or simply **conjugacy**.

Warning: While this terminology is standard in dynamical systems, the terms *conjugate* and *equivalent* are used differently in linear algebra. *Conjugacy* as used here is related to matrix similarity (cf. Fact 6), *not* to matrix conjugacy, and *equivalence* as used here is *not* related to matrix equivalence.

Facts:

Literature: [HSD04], [Rob98].

1. If the flows Φ and Ψ are C^k-conjugate, then they are C^k-equivalent.
2. Each time-t map φ_t has an inverse $(\varphi_t)^{-1} = \varphi_{-t}$, and $\varphi_t : M \longrightarrow M$ is a homeomorphism, i.e., a continuous bijective map with continuous inverse.
3. Denote the set of time-t maps again by $\Phi = \{\varphi_t,\ t \in \mathbb{R}\}$. A dynamical system is a group in the sense that $(\Phi, \circ)$, with $\circ$ denoting composition of maps, satisfies the group axioms, and $\varphi : (\mathbb{R}, +) \longrightarrow (\Phi, \circ)$, defined by $\varphi(t) = \varphi_t$, is a group homomorphism.
4. Let M be a C^∞-differentiable manifold and X a C^∞-vector field on M such that the differential equation $\dot{x} = X(x)$ has unique solutions $x(t, x_0)$ for all $x_0 \in M$ and all $t \in \mathbb{R}$, with $x(0, x_0) = x_0$. Then $\Phi(t, x_0) = x(t, x_0)$ defines a dynamical system $\Phi : \mathbb{R} \times M \longrightarrow M$.
5. A point $x_0 \in M$ is a fixed point of the dynamical system Φ associated with a differential equation $\dot{x} = X(x)$ as above if and only if $X(x_0) = 0$.
6. For two linear flows Φ (associated with $\dot{\mathbf{x}} = A\mathbf{x}$) and Ψ (associated with $\dot{\mathbf{x}} = B\mathbf{x}$) in $\mathbb{R}^d$, the following are equivalent:
   (a) Φ and Ψ are C^k-conjugate for $k \geq 1$.
   (b) Φ and Ψ are linearly conjugate, i.e., the conjugacy map h is a linear operator in $\mathrm{GL}(\mathbb{R}^d)$.
   (c) A and B are similar, i.e., $A = TBT^{-1}$ for some $T \in GL(d, \mathbb{R})$.
7. Each of the statements in Fact 6 implies that A and B have the same eigenvalue structure and (up to a linear transformation) the same generalized real eigenspace structure. In particular, the C^k-conjugacy classes are exactly the real Jordan canonical form equivalence classes in $gl(d, \mathbb{R})$.
8. For two linear flows Φ (associated with $\dot{\mathbf{x}} = A\mathbf{x}$) and Ψ (associated with $\dot{\mathbf{x}} = B\mathbf{x}$) in $\mathbb{R}^d$, the following are equivalent:

   (a) Φ and Ψ are C^k-equivalent for $k \geq 1$.

   (b) Φ and Ψ are linearly equivalent, i.e., the equivalence map h is a linear map in $\mathrm{GL}(\mathbb{R}^d)$.

   (c) $A = \alpha TBT^{-1}$ for some positive real number α and $T \in GL(d, \mathbb{R})$.
9. Each of the statements in Fact 8 implies that A and B have the same real Jordan structure and their eigenvalues differ by a positive constant. Hence, the C^k-equivalence classes are real Jordan canonical form equivalence classes modulo a positive constant.

10. The set of hyperbolic matrices is open and dense in $gl(d, \mathbb{R})$. A matrix A is hyperbolic if and only if it is structurally stable in $gl(d, \mathbb{R})$, i.e., there exists a neighborhood $U \subset gl(d, \mathbb{R})$ of A such that all $B \in U$ are topologically equivalent to A.
11. If A and B are hyperbolic, then the associated linear flows Φ and Ψ in $\mathbb{R}^d$ are C^0-equivalent (and C^0-conjugate) if and only if the dimensions of the stable subspaces (and, hence, the dimensions of the unstable subspaces) of A and B agree.
12. Suppose that all eigenvalues of A and B have zero real part. Then the associated linear flows in $\mathbb{R}^d$ are C^0-equivalent if and only if $A = \alpha TBT^{-1}$ for some real number $\alpha \neq 0$ and $T \in GL(d, \mathbb{R})$.

Examples:

1. Linear differential equations: For $A \in gl(d, \mathbb{R})$ the solutions of $\dot{\mathbf{x}} = A\mathbf{x}$ form a continuous dynamical system with time set $\mathbb{R}$ and state space $M = \mathbb{R}^d$: Here $\Phi : \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$ is defined by $\Phi(t, \mathbf{x}_0) = \mathbf{x}(t, \mathbf{x}_0) = e^{At}\mathbf{x}_0$.
2. Fixed points of linear differential equations: A point $\mathbf{x}_0 \in \mathbb{R}^d$ is a fixed point of the dynamical system Φ associated with the linear differential equation $\dot{\mathbf{x}} = A\mathbf{x}$ if and only if $\mathbf{x}_0 \in \ker A$, the kernel of A.
3. Periodic orbits of linear differential equations: The orbit $\Phi(t, \mathbf{x}_0) := \mathbf{x}(t, \mathbf{x}_0)$, $t \in \mathbb{R}$ is periodic with period $\widehat{t} > 0$ if and only if $\mathbf{x}_0$ is in the eigenspace of a nonzero complex eigenvalue with zero real part.
4. For each matrix $A \in gl(d, \mathbb{R})$ its associated linear flow in $\mathbb{R}^d$ is C^k-conjugate (and, hence, C^k-equivalent) for all $k \geq 0$ to the dynamical system associated with the Jordan form $J_A^{\mathbb{R}}$.

79.3 Chain Recurrence and Morse Decompositions of Dynamical Systems

A matrix $A \in gl(d, \mathbb{R})$ and, hence, a linear differential equation $\dot{\mathbf{x}} = A\mathbf{x}$ maps subspaces of $\mathbb{R}^d$ into subspaces of $\mathbb{R}^d$. Therefore, the matrix A also defines dynamical systems on spaces of subspaces, such as the Grassmann and the flag manifolds. These are nonlinear systems, but they can be studied via linear algebra, and vice versa; the behavior of these systems allows for the investigation of certain properties of the matrix A. The key topological concepts for the analysis of systems on compact spaces like the Grassmann and flag manifolds are chain recurrence, Morse decompositions, and attractor–repeller decompositions. This section concentrates on the first two approaches; the connection to attractor–repeller decompositions can be found, e.g., in [CK00, App. B2].

Definitions:

Given a dynamical system $\Phi : \mathbb{R} \times M \longrightarrow M$, for a subset $N \subset M$ the **α-limit set** is defined as $\alpha(N) = \{y \in M$, there exist sequences x_n in N and $t_n \to -\infty$ in $\mathbb{R}$ with $\lim_{n\to\infty} \Phi(t_n, x_n) = y\}$, and similarly the **$\omega$-limit set** of N is defined as $\omega(N) = \{y \in M$, there exist sequences x_n in N and $t_n \to \infty$ in $\mathbb{R}$ with $\lim_{n\to\infty} \Phi(t_n, x_n) = y\}$.

For a flow Φ on a complete metric space M and $\varepsilon,\ T > 0$, an **(ε, T)-chain** from $x \in M$ to $y \in M$ is given by

$$n \in \mathbb{N},\ x_0 = x, \ldots, x_n = y,\ T_0, \ldots, T_{n-1} > T$$

with

$$\mathrm{d}(\Phi(T_i, x_i), x_{i+1}) < \varepsilon \text{ for all } i,$$

where d is the metric on M.

A set $K \subset M$ is **chain transitive** if for all $x, y \in K$ and all $\varepsilon, T > 0$ there is an (ε, T)-chain from x to y.

The **chain recurrent set** $\mathcal{CR}$ is the set of all points that are chain reachable from themselves, i.e., $CR = \{x \in M$, for all $\varepsilon, T > 0$ there is an (ε, T)-chain from x to $x\}$.

A set $\mathcal{M} \subset M$ is a **chain recurrent component**, if it is a maximal (with respect to set inclusion) chain transitive set. In this case, $\mathcal{M}$ is a connected component of the chain recurrent set $\mathcal{CR}$.

For a flow Φ on a complete metric space M, a compact subset $K \subset M$ is called **isolated invariant**, if it is invariant and there exists a neighborhood N of K, i.e., a set N with $K \subset \operatorname{int} N$, such that $\Phi(t,x) \in N$ for all $t \in \mathbb{R}$ implies $x \in K$.

A **Morse decomposition** of a flow Φ on a complete metric space M is a finite collection $\{\mathcal{M}_i,\ i = 1,\ldots,l\}$ of nonvoid, pairwise disjoint, and isolated compact invariant sets such that

(i) For all $x \in M$, $\omega(x)$, $\alpha(x) \subset \bigcup_{i=1}^{l} \mathcal{M}_i$; and

(ii) Suppose there are $\mathcal{M}_{j_0}, \mathcal{M}_{j_1}, \ldots, \mathcal{M}_{j_n}$ and $x_1, \ldots, x_n \in M \setminus \bigcup_{i=1}^{l} \mathcal{M}_i$ with $\alpha(x_i) \subset \mathcal{M}_{j_{i-1}}$ and $\omega(x_i) \subset \mathcal{M}_{j_i}$ for $i = 1, \ldots, n$; then $\mathcal{M}_{j_0} \neq \mathcal{M}_{j_n}$.

The elements of a Morse decomposition are called **Morse sets**.

A Morse decomposition $\{\mathcal{M}_i,\ i = 1,\ldots,l\}$ is **finer** than another decomposition $\{\mathcal{N}_j,\ j = 1,\ldots,n\}$, if for all $\mathcal{M}_i$ there exists an index $j \in \{1,\ldots,n\}$ such that $\mathcal{M}_i \subset \mathcal{N}_j$.

Facts:

Literature: [Rob98], [CK00], [ACK05].

1. For a Morse decomposition $\{\mathcal{M}_i,\ i = 1,\ldots,l\}$ the relation $\mathcal{M}_i \prec \mathcal{M}_j$, given by $\alpha(x) \subset \mathcal{M}_i$ and $\omega(x) \subset \mathcal{M}_j$ for some $x \in M \backslash \cup_{i=1}^{l} \mathcal{M}_i$, induces an order.
2. Let Φ, $\Psi : \mathbb{R} \times M \longrightarrow M$ be two dynamical systems on a state space M and let $h : M \to M$ be a topological equivalence for Φ and Ψ. Then
   - (i) The point $p \in M$ is a fixed point of Φ if and only if $h(p)$ is a fixed point of Ψ;
   - (ii) The orbit $\Phi(\cdot, p)$ is closed if and only if $\Psi(\cdot, h(p))$ is closed;
   - (iii) If $K \subset M$ is an α-(or ω-) limit set of Φ from $p \in M$, then $h\,[K]$ is an α-(or ω-) limit set of Ψ from $h(p) \in M$.
   - (iv) Given, in addition, two dynamical systems $\Theta_{1,2} : \mathbb{R} \times N \longrightarrow N$, if $h : M \to M$ is a topological conjugacy for the flows Φ and Ψ on M, and $g : N \to N$ is a topological conjugacy for Θ_1 and Θ_2 on N, then the product flows $\Phi \times \Theta_1$ and $\Psi \times \Theta_2$ on $M \times N$ are topologically conjugate via $h \times g : M \times N \longrightarrow M \times N$. This result is, in general, not true for topological equivalence.
3. Topological equivalences (and conjugacies) on a compact metric space M map chain transitive sets onto chain transitive sets.
4. Topological equivalences map invariant sets onto invariant sets, and minimal closed invariant sets onto minimal closed invariant sets.
5. Topological equivalences map Morse decompositions onto Morse decompositions.

Examples:

1. Dynamical systems in $\mathbb{R}^1$: Any limit set $\alpha(x)$ and $\omega(x)$ from a single point x of a dynamical system in $\mathbb{R}^1$ consists of a single fixed point. The chain recurrent components (and the finest Morse decomposition) consist of single fixed points or intervals of fixed points. Any Morse set consists of fixed points and intervals between them.
2. Dynamical systems in $\mathbb{R}^2$: A nonempty, compact limit set of a dynamical system in $\mathbb{R}^2$, which contains no fixed points, is a closed, i.e., a periodic orbit (Poincaré–Bendixson). Any

nonempty, compact limit set of a dynamical system in $\mathbb{R}^2$ consists of fixed points, connecting orbits (such as homoclinic or heteroclinic orbits), and periodic orbits.

3. Consider the following dynamical system Φ in $\mathbb{R}^2\backslash\{0\}$, given by a differential equation in polar form for $r > 0$, $\theta \in [0, 2\pi)$, and $a \neq 0$:

$$\dot{r} = 1 - r, \ \dot{\theta} = a.$$

For each $\mathbf{x} \in \mathbb{R}^2\backslash\{0\}$ the ω-limit set is the circle $\omega(\mathbf{x}) = \mathbb{S}^1 = \{(r, \theta), \ r = 1, \ \theta \in [0, 2\pi)\}$. The state space $\mathbb{R}^2\backslash\{0\}$ is not compact, and α-limit sets exist only for $\mathbf{y} \in \mathbb{S}^1$, for which $\alpha(\mathbf{y}) = \mathbb{S}^1$.

4. Consider the flow Φ from the previous example and a second system Ψ, given by

$$\dot{r} = 1 - r, \quad \dot{\theta} = b$$

with $b \neq 0$. Then the flows Φ and Ψ are topologically equivalent, but not conjugate if $b \neq a$.

5. An example of a flow for which the limit sets from points are strictly contained in the chain recurrent components can be obtained as follows: Let $M = [0, 1] \times [0, 1]$. Let the flow Φ on M be defined such that all points on the boundary are fixed points, and the orbits for points $(x, y) \in (0, 1) \times (0, 1)$ are straight lines $\Phi(\cdot, (x, y)) = \{(z_1, z_2), \ z_1 = x, \ z_2 \in (0, 1)\}$ with $\lim_{t \to \pm\infty} \Phi(t, (x, y)) = (x, \pm 1)$. For this system, each point on the boundary is its own α- and ω-limit set. The α-limit sets for points in the interior $(x, y) \in (0, 1) \times (0, 1)$ are of the form $\{(x, -1)\}$, and the ω-limit sets are $\{(x, +1)\}$. The only chain recurrent component for this system is $M = [0, 1] \times [0, 1]$, which is also the only Morse set.

79.4 Linear Systems on Grassmannian and Flag Manifolds

Definitions:

The **kth Grassmannian** $\mathbb{G}_k$ of $\mathbb{R}^d$ can be defined via the following construction: Let $F(k, d)$ be the set of k-frames in $\mathbb{R}^d$, where a **k-frame** is an ordered set of k linearly independent vectors in $\mathbb{R}^d$. Two k-frames $X = [\mathbf{x}_1, \ldots, \mathbf{x}_k]$ and $Y = [\mathbf{y}_1, \ldots, \mathbf{y}_k]$ are said to be equivalent, $X \sim Y$, if there exists $T \in GL(k, \mathbb{R})$ with $X^T = TY^T$, where X and Y are interpreted as $d \times k$ matrices. The quotient space $\mathbb{G}_k = F(k, d)/\sim$ is a compact, $k(d-k)$-dimensional differentiable manifold. For $k = 1$, we obtain the projective space $\mathbb{P}^{d-1} = \mathbb{G}_1$ in $\mathbb{R}^d$.

The **kth flag** of $\mathbb{R}^d$ is given by the following $k-$sequences of subspace inclusions,

$$\mathbb{F}_k = \{F_k = (V_1, \ldots, V_k), V_i \subset V_{i+1} \text{ and } \dim V_i = i \text{ for all } i\}.$$

For $k = d$, this is the **complete flag** $\mathbb{F} = \mathbb{F}_d$.

Each matrix $A \in gl(d, \mathbb{R})$ defines a map on the subspaces of $\mathbb{R}^d$ as follows: Let $V = \text{Span}(\{\mathbf{x}_1, \ldots, \mathbf{x}_k\})$. Then $AV = \text{Span}(\{A\mathbf{x}_1, \ldots, A\mathbf{x}_k\})$.

Denote by $\mathbb{G}_k\Phi$ and $\mathbb{F}_k\Phi$ the induced flows on the Grassmannians and the flags, respectively.

Facts:

Literature: [Rob98], [CK00], [ACK05], [Kui75].

1. Let $\mathbb{P}\Phi$ be the projection onto $\mathbb{P}^{d-1}$ of a linear flow $\Phi(t, x) = e^{At}x$. Then $\mathbb{P}\Phi$ has l chain recurrent components $\{\mathcal{M}_1, \ldots, \mathcal{M}_l\}$, where l is the number of different Lyapunov exponents (i.e., of different real parts of eigenvalues) of A. For each Lyapunov exponent λ_i, $\mathcal{M}_i = \mathbb{P}L_i$, the projection of the ith Lyapunov space onto $\mathbb{P}^{d-1}$. Furthermore $\{\mathcal{M}_1, \ldots, \mathcal{M}_l\}$ defines the finest Morse decomposition of $\mathbb{P}\Phi$ and $\mathcal{M}_i \prec \mathcal{M}_j$ if and only if $\lambda_i < \lambda_j$.

2. For A, $B \in gl(d,\mathbb{R})$, let $\mathbb{P}\Phi$ and $\mathbb{P}\Psi$ be the associated flows on $\mathbb{P}^{d-1}$ and suppose that there is a topological equivalence h of $\mathbb{P}\Phi$ and $\mathbb{P}\Psi$. Then the chain recurrent components $\mathcal{N}_1,\dots,\mathcal{N}_n$ of $\mathbb{P}\Psi$ are of the form $\mathcal{N}_i = h[\mathcal{M}_i]$, where $\mathcal{M}_i$ is a chain recurrent component of $\mathbb{P}\Phi$. In particular, the number of chain recurrent components of $\mathbb{P}\Phi$ and $\mathbb{P}\Psi$ agree, and h maps the order on $\{\mathcal{M}_1,\dots,\mathcal{M}_l\}$ onto the order on $\{\mathcal{N}_1,\dots,\mathcal{N}_l\}$.
3. For A, $B \in gl(d,\mathbb{R})$ let $\mathbb{P}\Phi$ and $\mathbb{P}\Psi$ be the induced flows on $\mathbb{P}^{d-1}$. Then the characterization of topological conjugacies and equivalences of these flows appears as a very natural problem. However, apparently, this problem has not been solved. Related work [Kui76] on linear maps (instead of flows) shows that this is a very difficult problem. A weakening of topological conjugacy leads to the following characterization.
4. Two matrices A and B in $gl(d,\mathbb{R})$ have the same vector of the dimensions d_i of the Lyapunov spaces (in the natural order of their Lyapunov exponents) if and only if there exist a homeomorphism $h : \mathbb{P}^{d-1} \to \mathbb{P}^{d-1}$ that maps the finest Morse decomposition of $\mathbb{P}\Phi$ onto the finest Morse decomposition of $\mathbb{P}\Psi$, i.e., h maps Morse sets onto Morse sets and preserves their orders.
5. Let $A \in gl(d,\mathbb{R})$ with associated flows Φ on $\mathbb{R}^d$ and $\mathbb{F}_k\Phi$ on the k-flag.
   (i) For every $k \in \{1,\dots,d\}$ there exists a unique finest Morse decomposition $\{{}_k\mathcal{M}_{i_j}\}$ of $\mathbb{F}_k\Phi$, where $i_j \in \{1,\dots,d\}^k$ is a multi-index, and the number of chain transitive components in $\mathbb{F}_k$ is bounded by $\frac{d!}{(d-k)!}$.

   (ii) Let $\mathcal{M}_i$ with $i \in \{1,\dots,d\}^k$ be a chain recurrent component in $\mathbb{F}_{k-1}$. Consider the $(d-k+1)$-dimensional vector bundle $\pi : \mathcal{W}(\mathcal{M}_i) \to \mathcal{M}_i$ with fibers

   $$\mathcal{W}(\mathcal{M}_i)_{F_{k-1}} = \mathbb{R}^d/V_{k-1} \text{ for } F_k = (V_1,\dots,V_{k-1}) \in \mathcal{M}_i \subset \mathbb{F}_{k-1}.$$

   Then every chain recurrent component ${}_{\mathbb{P}}\mathcal{M}_{i_j}$, $j = 1,\dots,k_i \le d-k+1$, of the projective bundle $\mathbb{P}\mathcal{W}(\mathcal{M}_i)$ determines a chain recurrent component ${}_k\mathcal{M}_{i_j}$ on $\mathbb{F}_k$ via

   $${}_k\mathcal{M}_{i_j} = \left\{F_k = (F_{k-1},V_k) \in \mathbb{F}_k : F_{k-1} \in \mathcal{M}_i \text{ and } \mathbb{P}(V_k/V_{k-1}) \in {}_{\mathbb{P}}\mathcal{M}_{i_j}\right\}.$$

   Every chain recurrent component in $\mathbb{F}_k$ is of this form; this determines the multiindex i_j inductively for $k = 2,\dots,d$.
6. On every Grassmannian $\mathbb{G}_i$ there exists a finest Morse decomposition of the dynamical system $\mathbb{G}_i\Phi$. Its Morse sets are given by the projection of the chain recurrent components from the complete flag $\mathbb{F}$.
7. Let $A \in gl(d,\mathbb{R})$ be a matrix with flow Φ on $\mathbb{R}^d$. Let L_i, $i = 1,\dots,l$, be the Lyapunov spaces of A, i.e., their projections $\mathbb{P}L_i = \mathcal{M}_i$ are the finest Morse decomposition of $\mathbb{P}\Phi$ on the projective space. For $k = 1,\dots,d$ define the index set

   $$I(k) = \{(k_1,\dots,k_m) : k_1 + \ldots + k_m = k \text{ and } 0 \le k_i \le d_i = \dim L_i\}.$$

   Then the finest Morse decomposition on the Grassmannian $\mathbb{G}_k$ is given by the sets

   $$\mathcal{N}^k_{k_1,\dots,k_m} = \mathbb{G}_{k_1}L_1 \oplus \ldots . \oplus \mathbb{G}_{k_m}L_m,\ (k_1,\dots,k_m) \in I(k).$$
8. For two matrices $A, B \in gl(d,\mathbb{R})$ the vector of the dimensions d_i of the Lyapunov spaces (in the natural order of their Lyapunov exponents) are identical if and only if certain graphs defined on the Grassmannians are isomorphic; see [ACK05].

Examples:

1. For $A \in gl(d, \mathbb{R})$ let Φ be its linear flow in $\mathbb{R}^d$. The flow Φ projects onto a flow $\mathbb{P}\Phi$ on $\mathbb{P}^{d-1}$, given by the differential equation

$$\dot{s} = h(s, A) = (A - s^T As\ I)\ s, \text{ with } s \in \mathbb{P}^{d-1}.$$

Consider the matrices

$$A = \text{diag}(-1, -1, 1) \text{ and } B = \text{diag}(-1, 1, 1).$$

We obtain the following structure for the finest Morse decompositions on the Grassmannians for A:
$\mathbb{G}_1$: $\mathcal{M}_1 = \{\text{Span}(\mathbf{e}_1, \mathbf{e}_2)\}$ and $\mathcal{M}_3 = \{\text{Span}(\mathbf{e}_3)\}$
$\mathbb{G}_2$: $\mathcal{M}_{1,2} = \{\text{Span}(\mathbf{e}_1, \mathbf{e}_2)\}$ and $\mathcal{M}_{1,3} = \{\{\text{Span}(\mathbf{x}, \mathbf{e}_3)\} : \mathbf{x} \in \text{Span}(\mathbf{e}_1, \mathbf{e}_2)\}$
$\mathbb{G}_3$: $\mathcal{M}_{1,2,3} = \{\text{Span}(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)\}$
and for B we have
$\mathbb{G}_1$: $\mathcal{N}_1 = \{\text{Span}(\mathbf{e}_1)\}$ and $\mathcal{N}_2 = \{\text{Span}(\mathbf{e}_2, \mathbf{e}_3)\}$
$\mathbb{G}_2$: $\mathcal{N}_{1,2} = \{\text{Span}(\mathbf{e}_1, \mathbf{x}) : \mathbf{x} \in \text{Span}(\mathbf{e}_2, \mathbf{e}_3)\}$ and $\mathcal{N}_{2,3} = \{\text{Span}(\mathbf{e}_2, \mathbf{e}_3)\}$
$\mathbb{G}_3$: $\mathcal{N}_{1,2,3} = \{\text{Span}(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)\}$.

On the other hand, the Morse sets in the full flag are given for A and B by

$$\begin{bmatrix} \mathcal{M}_{1,2,3} \\ \mathcal{M}_{1,2} \\ \mathcal{M}_1 \end{bmatrix} \preceq \begin{bmatrix} \mathcal{M}_{1,2,3} \\ \mathcal{M}_{1,3} \\ \mathcal{M}_1 \end{bmatrix} \preceq \begin{bmatrix} \mathcal{M}_{1,2,3} \\ \mathcal{M}_{1,3} \\ \mathcal{M}_3 \end{bmatrix} \text{ and } \begin{bmatrix} \mathcal{N}_{1,2,3} \\ \mathcal{N}_{1,2} \\ \mathcal{N}_1 \end{bmatrix} \preceq \begin{bmatrix} \mathcal{N}_{1,2,3} \\ \mathcal{N}_{1,2} \\ \mathcal{N}_2 \end{bmatrix} \preceq \begin{bmatrix} \mathcal{N}_{1,2,3} \\ \mathcal{N}_{2,3} \\ \mathcal{N}_2 \end{bmatrix},$$

respectively. Thus, in the full flag, the numbers and the orders of the Morse sets coincide, while on the Grassmannians (together with the projection relations between different Grassmannians) one can distinguish also the dimensions of the corresponding Lyapunov spaces. (See [ACK05] for a precise statement.)

79.5 Linear Skew Product Flows

Developing a linear algebra for time varying systems $\dot{\mathbf{x}} = A(t)\mathbf{x}$ means defining appropriate concepts to generalize eigenvalues, linear eigenspaces and their dimensions, and certain normal forms that characterize the behavior of the solutions of a time varying system and that reduce to the constant matrix case if $A(t) \equiv A \in gl(d, \mathbb{R})$. The eigenvalues and eigenspaces of the family $\{A(t), t \in \mathbb{R}\}$ do not provide an appropriate generalization; see, e.g., [Hah67], Chapter 74. For certain classes of time varying systems it turns out that the Lyapunov exponents and Lyapunov spaces introduced in Section 79.1 capture the key properties of (real parts of) eigenvalues and of the associated subspace decomposition of $\mathbb{R}^d$. These systems are linear skew product flows for which the base is a (nonlinear) system θ_t that enters into the linear dynamics of a differential equation in the form $\dot{\mathbf{x}} = A(\theta_t)\mathbf{x}$. Examples for this type of system include periodic and almost periodic differential equations, random differential equations, systems over ergodic or chain recurrent bases, linear robust systems, and bilinear control systems. This section concentrates on periodic linear differential equations, random linear dynamical systems, and robust linear systems. It is written to emphasize the correspondences between the linear algebra in Section 79.1, Floquet theory, the multiplicative ergodic theorem, and the Morse spectrum and Selgrade's theorem.
Literature: [Arn98], [BK94], [CK00], [Con97], [Rob98].

Definitions:

A (continuous time) **linear skew-product flow** is a dynamical system with state space $M = \Omega \times \mathbb{R}^d$ and flow $\Phi : \mathbb{R} \times \Omega \times \mathbb{R}^d \longrightarrow \Omega \times \mathbb{R}^d$, where $\Phi = (\theta, \varphi)$ is defined as follows: $\theta : \mathbb{R} \times \Omega \longrightarrow \Omega$ is a dynamical system, and $\varphi : \mathbb{R} \times \Omega \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$ is linear in its $\mathbb{R}^d$-component, i.e., for each $(t, \omega) \in \mathbb{R} \times \Omega$ the map $\varphi(t, \omega, \cdot) : \mathbb{R}^d \longrightarrow \mathbb{R}^d$ is linear. Skew-product flows are called measurable (continuous, differentiable) if $\Omega = (\theta, \varphi)$ is a measurable space (topological space, differentiable manifold) and Φ is measurable (continuous, differentiable). For the time-t maps, the notation $\theta_t = \theta(t, \cdot) : \Omega \longrightarrow \Omega$ is used again.

Note that the **base component** $\theta : \mathbb{R} \times \Omega \longrightarrow \Omega$ is a dynamical system itself, while the **skew-component** φ is not a dynamical system. The skew-component φ is often called a **co-cycle** over θ.

Let $\Phi : \mathbb{R} \times \Omega \times \mathbb{R}^d \longrightarrow \Omega \times \mathbb{R}^d$ be a linear skew-product flow. For $\mathbf{x}_0 \in \mathbb{R}^d$, $\mathbf{x}_0 \neq 0$, the **Lyapunov exponent** is defined as $\lambda(\mathbf{x}_0, \omega) = \limsup_{t \to \infty} \frac{1}{t} \log \|\varphi(t, \omega, \mathbf{x}_0)\|$, where log denotes the natural logarithm and $\|\cdot\|$ is any norm in $\mathbb{R}^d$.

Examples:

1. Time varying linear differential equations: Let $A : \mathbb{R} \longrightarrow gl(d, \mathbb{R})$ be a uniformly continuous function and consider the linear differential equation $\dot{\mathbf{x}}(t) = A(t)\mathbf{x}(t)$. The solutions of this differential equation define a dynamical system via $\Phi : \mathbb{R} \times \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R} \times \mathbb{R}^d$, where $\theta : \mathbb{R} \times \mathbb{R} \longrightarrow \mathbb{R}$ is given by $\theta(t, \tau) = t + \tau$, and $\varphi : \mathbb{R} \times \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$ is defined as $\varphi(t, \tau, \mathbf{x}_0) = X(t+\tau, \tau)\mathbf{x}_0$. Here $X(t, \tau)$ is a fundamental matrix of the differential equation $\dot{X}(t) = A(t)X(t)$ in $gl(d, \mathbb{R})$. Note that for $\varphi(t, \tau, \cdot) : \mathbb{R}^d \longrightarrow \mathbb{R}^d$, $t \in \mathbb{R}$, we have $\varphi(t + s, \tau) = \varphi(t, \theta(s, \tau)) \circ \varphi(s, \tau)$ and, hence, the solutions of $\dot{\mathbf{x}}(t) = A(t)\mathbf{x}(t)$ themselves do not define a flow. The additional component θ "keeps track of time."
2. Metric dynamical systems: Let $(\Omega, \mathcal{F}, P)$ be a probability space, i.e., a set Ω with σ-algebra $\mathcal{F}$ and probability measure P. Let $\theta : \mathbb{R} \times \Omega \longrightarrow \Omega$ be a measurable flow such that the probability measure P is invariant under θ, i.e., $\theta_t P = P$ for all $t \in \mathbb{R}$, where for all measurable sets $X \in \mathcal{F}$ we define $\theta_t P(X) = P\{\theta_t^{-1}(X)\} = P(X)$. Flows of this form are often called metric dynamical systems.
3. Random linear dynamical systems: A random linear dynamical system is a skew-product flow $\Phi : \mathbb{R} \times \Omega \times \mathbb{R}^d \longrightarrow \Omega \times \mathbb{R}^d$, where $(\Omega, \mathcal{F}, P, \theta)$ is a metric dynamical system and each $\varphi : \mathbb{R} \times \Omega \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$ is linear in its $\mathbb{R}^d$-component. Examples for random linear dynamical systems are given, e.g., by linear stochastic differential equations or linear differential equations with stationary background noise; see [Arn98].
4. Robust linear systems: Consider a linear system with time varying perturbations of the form $\dot{\mathbf{x}} = A(u(t))\mathbf{x} := A_0\mathbf{x} + \sum_{i=1}^{m} u_i(t)A_i\mathbf{x}$, where $A_0, \ldots, A_m \in gl(d, \mathbb{R})$, $u \in \mathcal{U} = \{u : \mathbb{R} \longrightarrow U$, integrable on every bounded interval$\}$, and $U \subset \mathbb{R}^m$ is compact, convex with $0 \in \operatorname{int} U$. A robust linear system defines a linear skew-product flow via the following construction: We endow $\mathcal{U}$ with the weak*-topology of $L^\infty(\mathbb{R}, U)^*$ to make it a compact, metrizable space. The base component is defined as the shift $\theta : \mathbb{R} \times \mathcal{U} \longrightarrow \mathcal{U}$, $\theta(t, u(\cdot)) = u(\cdot + t)$, and the skew-component consists of the solutions $\varphi(t, u(\cdot), \mathbf{x})$, $t \in \mathbb{R}$ of the perturbed differential equation. Then $\Phi : \mathbb{R} \times \mathcal{U} \times \mathbb{R}^d \longrightarrow \mathcal{U} \times \mathbb{R}^d$, $\Phi(t, u, \mathbf{x}) = (\theta(t, u), \varphi(t, u, \mathbf{x}))$ defines a continuous linear skew-product flow. The functions u can also be considered as (open loop) controls.

79.6 Periodic Linear Differential Equations: Floquet Theory

Definitions:

A **periodic linear differential equation** $\dot{\mathbf{x}} = A(\theta_t)\mathbf{x}$ is given by a matrix function $A : \mathbb{R} \longrightarrow gl(d, \mathbb{R})$ that is continuous and periodic (of period $\widehat{t} > 0$). As above, the solutions define a dynamical system via $\Phi : \mathbb{R} \times \mathbb{S}^1 \times \mathbb{R}^d \longrightarrow \mathbb{S}^1 \times \mathbb{R}^d$, if we identify $\mathbb{R} \bmod \widehat{t}$ with the circle $\mathbb{S}^1$.

Facts:

Literature: [Ama90], [GH83], [Hah67], [Sto92], [Wig96].

1. Consider the periodic linear differential equation $\dot{\mathbf{x}} = A(\theta_t)\mathbf{x}$ with period $\widehat{t} > 0$. A fundamental matrix $X(t)$ of the system is of the form $X(t) = P(t)e^{Rt}$ for $t \in \mathbb{R}$, where $P(\cdot)$ is a nonsingular, differentiable, and $\widehat{t}$-periodic matrix function and $R \in gl(d, \mathbb{C})$.
2. Let $X(\cdot)$ be a fundamental solution with $X(0) = I \in GL(d, \mathbb{R})$. The matrix $X(\widehat{t}) = e^{R\widehat{t}}$ is called the monodromy matrix of the system. Note that R is, in general, not uniquely determined by X, and does not necessarily have real entries. The eigenvalues α_j, $j = 1, \ldots, d$ of $X(\widehat{t})$ are called the characteristic multipliers of the system, and the eigenvalues $\mu_j = \lambda_j + i\nu_j$ of R are the characteristic exponents. It holds that $\mu_j = \frac{1}{\widehat{t}} \log \alpha_j + \frac{2m\pi i}{\widehat{t}}$, $j = 1, \ldots, d$ and $m \in \mathbb{Z}$. This determines uniquely the real parts of the characteristic exponents $\lambda_j = \text{Re } \mu_j = \log |\alpha_j|$, $j = 1, \ldots, d$. The λ_j are called the Floquet exponents of the system.
3. Let $\Phi = (\theta, \varphi) : \mathbb{R} \times \mathbb{S}^1 \times \mathbb{R}^d \longrightarrow \mathbb{S}^1 \times \mathbb{R}^d$ be the flow associated with a periodic linear differential equation $\dot{\mathbf{x}} = A(t)\mathbf{x}$. The system has a finite number of Lyapunov exponents λ_j, $j = 1, \ldots, l \leq d$. For each exponent λ_j and each $\tau \in \mathbb{S}^1$ there exists a splitting $\mathbb{R}^d = \bigoplus_{j=1}^{l} L(\lambda_j, \tau)$ of $\mathbb{R}^d$ into linear subspaces with the following properties:
   (a) The subspaces $L(\lambda_j, \tau)$ have the same dimension independent of τ, i.e., for each $j = 1, \ldots, l$ it holds that $\dim L(\lambda_j, \sigma) = \dim L(\lambda_j, \tau) =: d_i$ for all $\sigma, \tau \in \mathbb{S}^1$.
   (b) The subspaces $L(\lambda_j, \tau)$ are invariant under the flow Φ, i.e., for each $j = 1, \ldots, l$ it holds that $\varphi(t, \tau)L(\lambda_j, \tau) = L(\lambda_j, \theta(t, \tau)) = L(\lambda_j, t + \tau)$ for all $t \in \mathbb{R}$ and $\tau \in \mathbb{S}^1$.
   (c) $\lambda(\mathbf{x}, \tau) = \lim_{t \to \pm\infty} \frac{1}{t} \log \|\varphi(t, \tau, \mathbf{x})\| = \lambda_j$ if and only if $\mathbf{x} \in L(\lambda_j, \tau) \backslash \{0\}$.
4. The Lyapunov exponents of the system are exactly the Floquet exponents. The linear subspaces $L(\lambda_j, \cdot)$ are called the Lyapunov spaces (or sometimes the Floquet spaces) of the periodic matrix function $A(t)$.
5. For each $j = 1, \ldots, l \leq d$ the map $L_j : \mathbb{S}^1 \longrightarrow \mathbb{G}_{d_j}$ defined by $\tau \longmapsto L(\lambda_j, \tau)$ is continuous.
6. These facts show that for periodic matrix functions $A : \mathbb{R} \longrightarrow gl(d, \mathbb{R})$ the Floquet exponents and Floquet spaces replace the real parts of eigenvalues and the Lyapunov spaces, concepts that are so useful in the linear algebra of (constant) matrices $A \in gl(d, \mathbb{R})$. The number of Lyapunov exponents and the dimensions of the Lyapunov spaces are constant for $\tau \in \mathbb{S}^1$, while the Lyapunov spaces themselves depend on the time parameter τ of the periodic matrix function $A(t)$, and they form periodic orbits in the Grassmannians $\mathbb{G}_{d_j}$ and in the corresponding flag.
7. As an application of these results, consider the problem of stability of the zero solution of $\dot{\mathbf{x}}(t) = A(t)\mathbf{x}(t)$ with period $\widehat{t} > 0$: The stable, center, and unstable subspaces associated with the periodic matrix function $A : \mathbb{R} \longrightarrow gl(d, \mathbb{R})$ are defined as $L^-(\tau) = \bigoplus\{L(\lambda_j, \tau),\ \lambda_j < 0\}$, $L^0(\tau) = \bigoplus\{L(\lambda_j, \tau),\ \lambda_j = 0\}$, and $L^+(\tau) = \bigoplus\{L(\lambda_j, \tau),\ \lambda_j > 0\}$, respectively, for $\tau \in \mathbb{S}^1$. The zero solution $\mathbf{x}(t, 0) \equiv 0$ of the periodic linear differential equation $\dot{\mathbf{x}} = A(t)\mathbf{x}$ is asymptotically stable if and only if it is exponentially stable if and only if all Lyapunov exponents are negative if and only if $L^-(\tau) = \mathbb{R}^d$ for some (and hence for all) $\tau \in \mathbb{S}^1$.
8. Another approach to the study of time-dependent linear differential equations is via transforming an equation with bounded coefficients into an equation of known type, such as equations with constant coefficients. Such transformations are known as Lyapunov transformations; see [Hah67, Sects. 61–63].

Examples:

1. Consider the $\widehat{t}$-periodic differential equation $\dot{\mathbf{x}} = A(t)\mathbf{x}$. This equation has a nontrivial $\widehat{t}$-periodic solution iff the system has a characteristic multiplier equal to 1; see Example 2.3 for the case with constant coefficients [Ama90, Prop. 20.12].
2. Let H be a continuous quadratic form in $2d$ variables $x_1, \ldots, x_d, y_1, \ldots, y_d$ and consider the Hamiltonian system
$$\dot{x}_i = \frac{\partial H}{\partial y_i},\ \dot{y}_i = -\frac{\partial H}{\partial x_i},\ i = 1, \ldots, d.$$
Using $\mathbf{z}^T = [\mathbf{x}^T, \mathbf{y}^T]$, we can set $H(\mathbf{x}, \mathbf{y}, t) = \mathbf{z}^T A(t)\mathbf{z}$, where $A = \begin{bmatrix} A_{11} & A_{12} \\ A_{12}^T & A_{22} \end{bmatrix}$ with A_{11} and A_{22} symmetric, and, hence, the equation takes the form
$$\dot{\mathbf{z}} = \begin{bmatrix} A_{12}^T(t) & A_{22}(t) \\ -A_{11}(t) & -A_{12}(t) \end{bmatrix} \mathbf{z} =: P(t)\mathbf{z}.$$
Note that $-P^T(t) = QP(t)Q^{-1}$ with $Q = \begin{bmatrix} 0 & -I \\ I & 0 \end{bmatrix}$, where I is the $d \times d$ identity matrix. Assume that H is $\widehat{t}$-periodic, then the equation for z and its adjoint have the same Floquet exponents and for each exponent λ its negative $-\lambda$ is also a Floquet exponent. Hence, the fixed point $0 \in \mathbb{R}^{2d}$ cannot be exponentially stable [Hah67, Sect. 60].
3. Consider the periodic linear oscillator
$$\ddot{y} + q_1(t)\dot{y} + q_2(t)y = 0.$$
Using the substitution $y = z \exp(-\frac{1}{2}\int q_1(u)du)$ one obtains Hill's differential equation
$$\ddot{z} + p(t)z = 0,\ p(t) := q_2(t) - \frac{1}{4}q_1(t)^2 - \frac{1}{2}\dot{q}_1(t).$$
Its characteristic equation is $\lambda^2 - 2a\lambda + 1 = 0$, with a still to be determined. The multipliers satisfy the relations $\alpha_1\alpha_2 = 1$ and $\alpha_1 + \alpha_2 = 2a$. The exponential stability of the system can be analyzed using the parameter a: If $a^2 > 1$, then one of the multipliers has absolute value > 1 and, hence, the system has an unbounded solution. If $a^2 = 1$, then the system has a nontrivial periodic solution according to Example 1. If $a^2 < 1$, then the system is stable. The parameter a can often be expressed in the form of a power series; see [Hah67, Sect. 62] for more details. A special case of Hill's equation is the Mathieu equation
$$\ddot{z} + (\beta_1 + \beta_2 \cos 2t)z = 0,$$
with β_1, β_2 real parameters. For this equation numerically computed stability diagrams are available; see [Sto92, Sects. VI. 3 and 4].

79.7 Random Linear Dynamical Systems

Definitions:

Let $\theta : \mathbb{R} \times \Omega \longrightarrow \Omega$ be a metric dynamical system on the probability space $(\Omega, \mathcal{F}, P)$. A set $\Delta \in \mathcal{F}$ is called **P-invariant under θ** if $P[(\theta^{-1}(t, \Delta) \setminus \Delta) \cup (\Delta \setminus \theta^{-1}(t, \Delta))] = 0$ for all $t \in \mathbb{R}$. The flow θ is called **ergodic**, if each invariant set $\Delta \in \mathcal{F}$ has P-measure 0 or 1.

Facts:

Literature: [Arn98], [Con97].

1. (Oseledets Theorem, Multiplicative Ergodic Theorem) Consider a random linear dynamical system $\Phi = (\theta, \varphi) : \mathbb{R} \times \Omega \times \mathbb{R}^d \longrightarrow \Omega \times \mathbb{R}^d$ and assume

   $$\sup_{0 \leq t \leq 1} \log^+ \|\varphi(t,\omega)\| \in \mathcal{L}^1(\Omega, \mathcal{F}, \mathbb{P}) \text{ and } \sup_{0 \leq t \leq 1} \log^+ \left\|\varphi(t,\omega)^{-1}\right\| \in \mathcal{L}^1(\Omega, \mathcal{F}, \mathbb{P}),$$

   where $\| \cdot \|$ is any norm on $GL(d,\mathbb{R})$, $\mathcal{L}^1$ is the space of integrable functions, and $\log^+$ denotes the positive part of log, i.e.,

   $$\log^+(x) = \begin{cases} \log(x) & \text{for } \log(x) > 0 \\ 0 & \text{for } \log(x) \leq 0. \end{cases}$$

   Then there exists a set $\widehat{\Omega} \subset \Omega$ of full P-measure, invariant under the flow $\theta : \mathbb{R} \times \Omega \longrightarrow \Omega$, such that for each $\omega \in \widehat{\Omega}$ there is a splitting $\mathbb{R}^d = \bigoplus_{j=1}^{l(\omega)} L_j(\omega)$ of $\mathbb{R}^d$ into linear subspaces with the following properties:

   (a) The number of subspaces is θ-invariant, i.e., $l(\theta(t,\omega)) = l(\omega)$ for all $t \in \mathbb{R}$, and the dimensions of the subspaces are θ-invariant, i.e., $\dim L_j(\theta(t,\omega)) = \dim L_j(\omega) =: d_j(\omega)$ for all $t \in \mathbb{R}$.

   (b) The subspaces are invariant under the flow Φ, i.e., $\varphi(t,\omega)L_j(\omega) \subset L_j(\theta(t,\omega))$ for all $j = 1, \ldots, l(\omega)$.

   (c) There exist finitely many numbers $\lambda_1(\omega) < \ldots < \lambda_{l(\omega)}(\omega)$ in $\mathbb{R}$, such that for each $\mathbf{x} \in \mathbb{R}^d \backslash \{0\}$ the Lyapunov exponent $\lambda(\mathbf{x}, \omega)$ exists as a limit and $\lambda(\mathbf{x}, \omega) = \lim_{t \to \pm\infty} \frac{1}{t} \log \|\varphi(t, \tau, \mathbf{x})\| = \lambda_j(\omega)$ if and only if $\mathbf{x} \in L_j(\omega) \backslash \{0\}$. The subspaces $L_j(\omega)$ are called the Lyapunov (or sometimes the Oseledets) spaces of the system Φ.

2. The following maps are measurable: $l : \Omega \longrightarrow \{1, \ldots, d\}$ with the discrete σ-algebra, and for each $j = 1, \ldots, l(\omega)$ the maps $L_j : \Omega \longrightarrow \mathbb{G}_{d_j}$ with the Borel σ-algebra, $d_j : \Omega \longrightarrow \{1, \ldots, d\}$ with the discrete σ-algebra, and $\lambda_j : \Omega \longrightarrow \mathbb{R} \cup \{-\infty\}$ with the (extended) Borel σ-algebra.
3. If the base flow $\theta : \mathbb{R} \times \Omega \longrightarrow \Omega$ is ergodic, then the maps l, d_j, and λ_j are constant on $\widehat{\Omega}$, but the Lyapunov spaces $L_j(\omega)$ still depend (in a measurable way) on $\omega \in \widehat{\Omega}$.
4. As an application of these results, we consider random linear differential equations: Let $(\Gamma, \mathcal{E}, Q)$ be a probability space and $\xi : \mathbb{R} \times \Gamma \longrightarrow \mathbb{R}^m$ a stochastic process with continuous trajectories, i.e., the functions $\xi(\cdot, \gamma) : \mathbb{R} \longrightarrow \mathbb{R}^m$ are continuous for all $\gamma \in \Gamma$. The process ξ can be written as a measurable dynamical system in the following way: Define $\Omega = \mathcal{C}(\mathbb{R}, \mathbb{R}^m)$, the space of continuous functions from $\mathbb{R}$ to $\mathbb{R}^m$. We denote by $\mathcal{F}$ the σ-algebra on Ω generated by the cylinder sets, i.e., by sets of the form $Z = \{\omega \in \Omega,\ \omega(t_1) \in F_1, \ldots, \omega(t_n) \in F_n,\ n \in \mathbb{N},\ F_i$ Borel sets in $\mathbb{R}^m\}$. The process ξ induces a probability measure P on $(\Omega, \mathcal{F})$ via $P(Z) = Q\{\gamma \in \Gamma, \xi(t_i, \gamma) \in F_i$ for $i = 1, \ldots, n\}$. Define the shift $\theta : \mathbb{R} \times \Omega \longrightarrow \mathbb{R} \times \Omega$ as $\theta(t, \omega(\cdot)) = \omega(t + \cdot)$. Then $(\Omega, \mathcal{F}, P, \theta)$ is a measurable dynamical system. If ξ is stationary, i.e., if for all $n \in \mathbb{N}$, and $t, t_1, \ldots, t_n \in \mathbb{R}$, and all Borel sets $F_1, \ldots, F_n$ in $\mathbb{R}^m$, it holds that $Q\{\gamma \in \Gamma,\ \xi(t_i, \gamma) \in F_i$ for $i = 1, \ldots, n\} = Q\{\gamma \in \Gamma,\ \xi(t_i + t, \gamma) \in F_i$ for $i = 1, \ldots, n\}$, then the shift θ on Ω is P-invariant, and $(\Omega, \mathcal{F}, P, \theta)$ is a metric dynamical system.
5. Let $A : \Omega \longrightarrow gl(d, \mathbb{R})$ be measurable with $A \in \mathcal{L}^1$. Consider the random linear differential equation $\dot{\mathbf{x}}(t) = A(\theta(t, \omega))\mathbf{x}(t)$, where $(\Omega, \mathcal{F}, P, \theta)$ is a metric dynamical system as described before. We understand the solutions of this equation to be ω-wise. Then the solutions define a random linear dynamical system. Since we assume that

$A \in \mathcal{L}^1$, this system satisfies the integrability conditions of the Multiplicative Ergodic Theorem.

6. Hence, for random linear differential equations $\dot{\mathbf{x}}(t) = A(\theta(t,\omega))\mathbf{x}(t)$ the Lyapunov exponents and the associated Oseledets spaces replace the real parts of eigenvalues and the Lyapunov spaces of constant matrices $A \in gl(d,\mathbb{R})$. If the "background" process ξ is ergodic, then all the quantities in the Multiplicative Ergodic Theorem are constant, except for the Lyapunov spaces that do, in general, depend on chance.
7. The problem of stability of the zero solution of $\dot{\mathbf{x}}(t) = A(\theta(t,\omega))\mathbf{x}(t)$ can now be analyzed in analogy to the case of a constant matrix or a periodic matrix function: The stable, center, and unstable subspaces associated with the random matrix process $A(\theta(t,\omega))$ are defined as $L^-(\omega) = \bigoplus\{L_j(\omega),\ \lambda_j(\omega) < 0\}$, $L^0(\omega) = \bigoplus\{L_j(\omega),\ \lambda_j(\omega) = 0\}$, and $L^+(\omega) = \bigoplus\{L_j(\omega),\ \lambda_j(\omega) > 0\}$, respectively for $\omega \in \widehat{\Omega}$. We obtain the following characterization of stability: The zero solution $\mathbf{x}(t,\omega,0) \equiv 0$ of the random linear differential equation $\dot{\mathbf{x}}(t) = A(\theta(t,\omega))\mathbf{x}(t)$ is P-almost surely exponentially stable if and only if P-almost surely all Lyapunov exponents are negative if and only if $P\{\omega \in \Omega,\ L^-(\omega) = \mathbb{R}^d\} = 1$.

Examples:

1. The case of constant matrices: Let $A \in gl(d,\mathbb{R})$ and consider the dynamical system $\varphi : \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$ generated by the solutions of the linear differential equation $\dot{\mathbf{x}} = A\mathbf{x}$. The flow φ can be considered as the skew-component of a random linear dynamical system over the base flow given by $\Omega = \{0\}$, $\mathcal{F}$ the trivial σ-algebra, P the Dirac measure at $\{0\}$, and $\theta : \mathbb{R} \times \Omega \longrightarrow \Omega$ defined as the constant map $\theta(t,\omega) = \omega$ for all $t \in \mathbb{R}$. Since the flow is ergodic and satisfies the integrability condition, we can recover all the results on Lyapunov exponents and Lyapunov spaces for φ from the Multiplicative Ergodic Theorem.
2. Weak Floquet Theory: Let $A : \mathbb{R} \longrightarrow gl(d,\mathbb{R})$ be a continuous, periodic matrix function. Define the base flow as follows: $\Omega = \mathbb{S}^1$, $\mathcal{B}$ is the Borel σ-algebra on $\mathbb{S}^1$, P is the uniform distribution on $\mathbb{S}^1$, and θ is the shift $\theta(t,\tau) = t + \tau$. Then $(\Omega, \mathcal{F}, P, \theta)$ is an ergodic metric dynamical system. The solutions $\varphi(\cdot,\tau,\mathbf{x})$ of $\dot{\mathbf{x}} = A(t)\mathbf{x}$ define a random linear dynamical system $\Phi : \mathbb{R} \times \Omega \times \mathbb{R}^d \longrightarrow \Omega \times \mathbb{R}^d$ via $\Phi(t,\omega,\mathbf{x}) = (\theta(t,\omega), \varphi(t,\omega,\mathbf{x}))$. With this set-up, the Multiplicative Ergodic Theorem recovers the results of Floquet Theory with P-probability 1.
3. Average Lyapunov exponent: In general, Lyapunov exponents for random linear systems are difficult to compute explicitly — numerical methods are usually the way to go. In the ergodic case, the average Lyapunov exponent $\overline{\lambda} := \frac{1}{d}\sum d_j\lambda_j$ is given by $\overline{\lambda} = \frac{1}{d} trE(A \mid \mathcal{I})$, where $A : \Omega \longrightarrow gl(d,\mathbb{R})$ is the random matrix of the system, and $E(\cdot,\mathcal{I})$ is the conditional expectation of the probability measure P given the σ-algebra $\mathcal{I}$ of invariant sets on Ω. As an example, consider the linear oscillator with random restoring force

$$\ddot{y}(t) + 2\beta\dot{y}(t) + (1 + \sigma f(\theta(t,\omega)))y(t) = 0,$$

where $\beta, \sigma \in \mathbb{R}$ are positive constants and $f : \Omega \to \mathbb{R}$ is in $\mathcal{L}^1$. We assume that the background process is ergodic. Using the notation $x_1 = y$ and $x_2 = \dot{y}$ we can write the equation as

$$\dot{\mathbf{x}}(t) = A(\theta(t,\omega)\mathbf{x}(t) = \begin{bmatrix} 0 & 1 \\ -1 - \sigma f(\theta(t,\omega)) & -2\beta \end{bmatrix} \mathbf{x}(t).$$

For this system we obtain $\overline{\lambda} = -\beta$ ([Arn98, Remark 3.3.12]).

79.8 Robust Linear Systems

Definitions:

Let $\Phi : \mathbb{R}\times\mathcal{U}\times\mathbb{R}^d \longrightarrow \mathcal{U}\times\mathbb{R}^d$ be a linear skew-product flow with continuous base flow $\theta : \mathbb{R}\times\mathcal{U} \longrightarrow \mathcal{U}$. Throughout this section, $\mathcal{U}$ is compact and θ is chain recurrent on $\mathcal{U}$. Denote by $\mathcal{U} \times \mathbb{P}^{d-1}$ the projective bundle and recall that Φ induces a dynamical system $\mathbb{P}\Phi : \mathbb{R} \times \mathcal{U} \times \mathbb{P}^{d-1} \longrightarrow \mathcal{U} \times \mathbb{P}^{d-1}$. For ε, $T > 0$ an (ε, T)-chain ζ of $\mathbb{P}\Phi$ is given by $n \in \mathbb{N}$, $T_0, \ldots, T_n \geq T$, and $(u_0, p_0), \ldots, (u_n, p_n) \in \mathcal{U} \times \mathbb{P}^{d-1}$ with $d(\mathbb{P}\Phi(T_i, u_i, p_i), (u_{i+1}, p_{i+1})) < \varepsilon$ for $i = 0, \ldots, n-1$.

Define the **finite time exponential growth rate** of such a chain ζ (or **chain exponent**) by

$$\lambda(\zeta) = \left(\sum_{i=0}^{n-1} T_i\right)^{-1} \sum_{i=0}^{n-1} \left(\log \|\varphi(T_i, x_i, u_i)\| - \log \|x_i\|\right),$$

where $x_i \in \mathbb{P}^{-1}(p_i)$.

Let $\mathcal{M} \subset \mathcal{U}\times\mathbb{P}^{d-1}$ be a chain recurrent component of the flow $\mathbb{P}\Phi$. Define the **Morse spectrum over** $\mathcal{M}$ as

$$\Sigma_{Mo}(\mathcal{M}) = \left\{ \begin{array}{c} \lambda \in \mathbb{R}, \text{ there exist sequences } \varepsilon_n \to 0,\ T_n \to \infty \text{ and} \\ (\varepsilon_n, T_n)\text{-chains } \zeta_n \text{ in } \mathcal{M} \text{ such that } \lim \lambda(\zeta_n) = \lambda \end{array} \right\}$$

and the **Morse spectrum of the flow** as

$$\Sigma_{Mo}(\Phi) = \left\{ \begin{array}{c} \lambda \in \mathbb{R}, \text{ there exist sequences } \varepsilon_n \to 0,\ T_n \to \infty \text{ and } (\varepsilon_n, T_n)\text{-} \\ \text{chains } \zeta_n \text{ in the chain recurrent set of } \mathbb{P}\Phi \text{ such that } \lim \lambda(\zeta_n) = \lambda \end{array} \right\}.$$

Define the **Lyapunov spectrum over** $\mathcal{M}$ as

$$\Sigma_{Ly}(\mathcal{M}) = \{\lambda(u, x),\ (u, x) \in \mathcal{M},\ x \neq 0\}$$

and the **Lyapunov spectrum of the flow** Φ as

$$\Sigma_{Ly}(\Phi) = \{\lambda(u, \mathbf{x}),\ (u, \mathbf{x}) \in \mathcal{U} \times \mathbb{R}^d,\ \mathbf{x} \neq 0\}.$$

Facts:

Literature: [CK00], [Gru96], [HP05].

1. The projected flow $\mathbb{P}\Phi$ has a finite number of chain-recurrent components $\mathcal{M}_1, \ldots, \mathcal{M}_l$, $l \leq d$. These components form the finest Morse decomposition for $\mathbb{P}\Phi$, and they are linearly ordered $\mathcal{M}_1 \prec \ldots \prec \mathcal{M}_l$. Their lifts $\mathbb{P}^{-1}\mathcal{M}_i \subset \mathcal{U} \times \mathbb{R}^d$ form a continuous subbundle decomposition of $\mathcal{U} \times \mathbb{R}^d = \bigoplus_{i=1}^{l} \mathbb{P}^{-1}\mathcal{M}_i$.
2. The Lyapunov spectrum and the Morse spectrum are defined on the Morse sets, i.e., $\Sigma_{Ly}(\Phi) = \bigcup_{i=1}^{l} \Sigma_{Ly}(\mathcal{M}_i)$ and $\Sigma_{Mo}(\Phi) = \bigcup_{i=1}^{l} \Sigma_{Mo}(\mathcal{M}_i)$.
3. For each Morse set $\mathcal{M}_i$ the Lyapunov spectrum is contained in the Morse spectrum, i.e., $\Sigma_{Ly}(\mathcal{M}_i) \subset \Sigma_{Mo}(\mathcal{M}_i)$ for $i = 1, \ldots, l$.
4. For each Morse set, its Morse spectrum is a closed, bounded interval $\Sigma_{Mo}(\mathcal{M}_i) = [\kappa_i^*, \kappa_i]$, and $\kappa_i^*, \kappa_i \in \Sigma_{Ly}(\mathcal{M})$ for $i = 1, \ldots, l$.

5. The intervals of the Morse spectrum are ordered according to the order of the Morse sets, i.e., $\mathcal{M}_i \prec \mathcal{M}_j$ is equivalent to $\kappa_i^* < \kappa_j^*$ and $\kappa_i < \kappa_j$.
6. As an application of these results, consider robust linear systems of the form $\Phi : \mathbb{R} \times \mathcal{U} \times \mathbb{R}^d \longrightarrow \mathcal{U} \times \mathbb{R}^d$, given by a perturbed linear differential equation $\dot{\mathbf{x}} = A(u(t))\mathbf{x} := A_0\mathbf{x} + \sum_{i=1}^m u_i(t)A_i\mathbf{x}$, with $A_0, \ldots, A_m \in gl(d, \mathbb{R})$, $u \in \mathcal{U} = \{u : \mathbb{R} \longrightarrow U$, integrable on every bounded interval$\}$ and $U \subset \mathbb{R}^m$ is compact, convex with $0 \in intU$. Explicit equations for the induced perturbed system on the projective space $\mathbb{P}^{d-1}$ can be obtained as follows: Let $\mathbb{S}^{d-1} \subset \mathbb{R}^d$ be the unit sphere embedded into $\mathbb{R}^d$. The projected system on $\mathbb{S}^{d-1}$ is given by

$$\dot{s}(t) = h(u(t), s(t)),\ u \in \mathcal{U},\ s \in \mathbb{S}^{d-1}$$

where

$$h(u, s) = h_0(s) + \sum_{i=1}^{m} u_i h_i(s) \text{ with } h_i(s) = \left(A_i - s^T A_i s \cdot I\right) s,\ i = 0, 1, \ldots, m.$$

Define an equivalence relation on $\mathbb{S}^{d-1}$ via $s_1 \sim s_2$ if $s_1 = -s_2$, identifying opposite points. Then the projective space can be identified as $\mathbb{P}^{d-1} = \mathbb{S}^{d-1}/\sim$. Since $h(u, s) = -h(u, -s)$, the differential equation also describes the projected system on $\mathbb{P}^{d-1}$. For the Lyapunov exponents one obtains in the same way

$$\lambda(u, \mathbf{x}) = \limsup_{t \to \infty} \frac{1}{t} \log \|\mathbf{x}(t)\| = \limsup_{t \to \infty} \frac{1}{t} \int_0^t q(u(\tau), s(\tau))\, d\tau$$

with

$$q(u, s) = q_0(s) + \sum_{i=1}^{m} u_i q_i(s) \text{ with } q_i(s) = \left(A_i - s^T A_i s \cdot I\right) s,\ \ i = 0, 1, \ldots, m.$$

For a constant perturbation $u(t) \equiv u \in \mathbb{R}$ for all $t \in \mathbb{R}$ the corresponding Lyapunov exponents $\lambda(u, \mathbf{x})$ of the flow Φ are the real parts of the eigenvalues of the matrix $A(u)$ and the corresponding Lyapunov spaces are contained in the subbundles $\mathbb{P}^{-1}\mathcal{M}_i$. Similarly, if a perturbation $u \in \mathcal{U}$ is periodic, the Floquet exponents of $\dot{\mathbf{x}} = A(u(\cdot))\mathbf{x}$ are part of the Lyapunov (and, hence, of the Morse) spectrum of the flow Φ, and the Floquet spaces are contained in $\mathbb{P}^{-1}\mathcal{M}_i$. The systems treated in this example can also be considered as "bilinear control systems" and studied relative to their control behavior and (exponential) stabilizability — this is the point of view taken in [CK00].
7. For robust linear systems "generically" the Lyapunov spectrum and the Morse spectrum agree; see [CK00] for a precise definition of "generic" in this context.
8. Of particular interest is the upper spectral interval $\Sigma_{Mo}(\mathcal{M}_l) = [\kappa_l^*, \kappa_l]$, as it determines the robust stability of $\dot{\mathbf{x}} = A(u(t))\mathbf{x}$ (and stabilizability of the system if the set $\mathcal{U}$ is interpreted as a set of admissible control functions; see [Gru96]). The stable, center, and unstable subbundles of $\mathcal{U} \times \mathbb{R}^d$ associated with the perturbed linear system $\dot{\mathbf{x}} = A(u(t))\mathbf{x}$ are defined as $L^- = \bigoplus\{\mathbb{P}^{-1}\mathcal{M}_j,\ \kappa_j < 0\}$, $L^0 = \bigoplus\{\mathbb{P}^{-1}\mathcal{M}_j,\ 0 \in [\kappa_j^*, \kappa_j]\}$, and $L^+ = \bigoplus\{\mathbb{P}^{-1}\mathcal{M}_j,\ \kappa_j^* > 0\}$, respectively. The zero solution of $\dot{\mathbf{x}} = A(u(t))\mathbf{x}$ is exponentially stable for all perturbations $u \in \mathcal{U}$ if and only if $\kappa_l < 0$ if and only if $L^- = \mathcal{U} \times \mathbb{R}^d$.

Examples:

1. In general, it is not possible to compute the Morse spectrum and the associated subbundle decompositions explicitly, even for relatively simple systems, and one has to revert to numerical algorithms; compare [CK00, App. D]. Let us consider, e.g., the linear oscillator with

uncertain restoring force

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1 & -2b \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + u(t) \begin{bmatrix} 0 & 0 \\ -1 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$$

with $u(t) \in [-\rho, \rho]$ and $b > 0$. Figure 79.1 shows the spectral intervals for this system depending on $\rho \geq 0$.

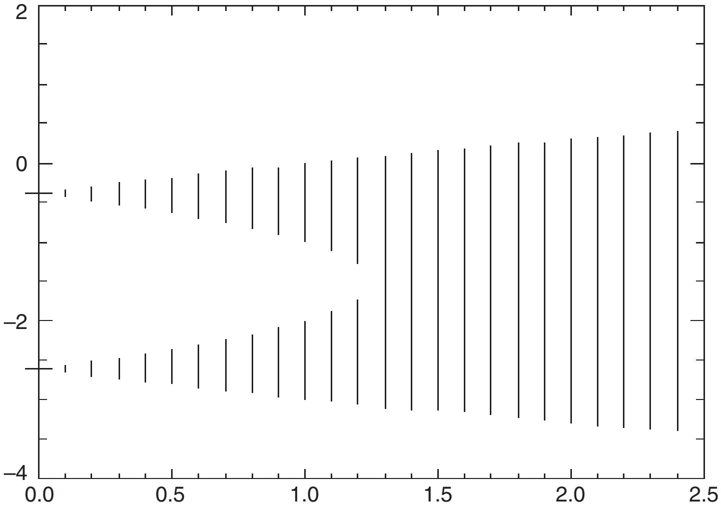

FIGURE 79.1 Spectral intervals depending on $\rho \geq 0$ for the system in Example 1.

2. We consider robust linear systems as described in Fact 6, with varying perturbation range by introducing the family $U^\rho = \rho U$ for $\rho \geq 0$. The resulting family of systems is

$$\dot{\mathbf{x}}^\rho = A(u^\rho(t))\mathbf{x}^\rho := A_0\mathbf{x}^\rho + \sum_{i=1}^{m} u_i^\rho(t) A_i \mathbf{x}^\rho,$$

with $u^\rho \in \mathcal{U}^\rho = \{u : \mathbb{R} \longrightarrow U^\rho$, integrable on every bounded interval$\}$. The corresponding maximal spectral value $\kappa_l(\rho)$ is continuous in ρ and we define the (asymptotic) stability radius of this family as $r = \inf\{\rho \geq 0$, there exists $u_0 \in \mathcal{U}^\rho$ such that $\dot{x}^\rho = A(u_0(t))x^\rho$ is not exponentially stable$\}$. This stability radius is based on asymptotic stability under all time varying perturbations. Similarly one can introduce stability radii based on time invariant perturbations (with values in $\mathbb{R}^m$ or $\mathbb{C}^m$) or on quadratic Lyapunov functions ([CK00], Chapter 17 and [HP05]).

3. Linear oscillator with uncertain damping: Consider the oscillator

$$\ddot{y} + 2(b + u(t))\dot{y} + (1 + c)y = 0$$

with $u(t) \in [-\rho, \rho]$ and $c \in \mathbb{R}$. In equivalent first-order form the system reads

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1-c & -2b \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + u(t) \begin{bmatrix} 0 & 0 \\ 0 & -2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}.$$

Clearly, the system is not exponentially stable for $c \leq -1$ with $\rho = 0$, and for $c > -1$ with $\rho \geq b$. It turns out that the stability radius for this system is

$$r(c) = \begin{cases} 0 & \text{for} \quad c \leq -1 \\ b & \text{for} \quad c > -1. \end{cases}$$

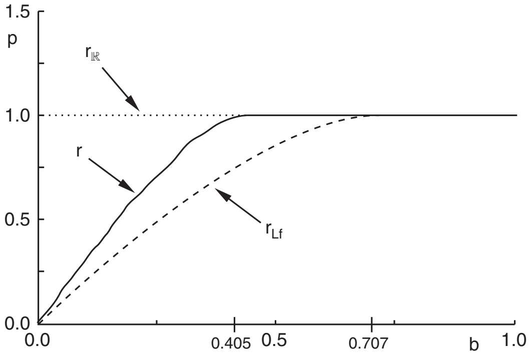

FIGURE 79.2 Stability radii for the system in Example 4.

4. Linear oscillator with uncertain restoring force: Here we look again at a system of the form

$$\begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -1 & -2b \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + u(t) \begin{bmatrix} 0 & 0 \\ -1 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}$$

with $u(t) \in [-\rho, \rho]$ and $b > 0$. (For $b \leq 0$ the system is unstable even for constant perturbations.) A closed form expression of the stability radius for this system is not available and one has to use numerical methods for the computation of (maximal) Lyapunov exponents (or maxima of the Morse spectrum); compare [CK00, App. D]. Figure 79.2 shows the (asymptotic) stability radius r, the stability radius under constant real perturbations $r_{\mathbb{R}}$, and the stability radius based on quadratic Lyapunov functions r_{Lf}, all in dependence on $b > 0$; see [CK00, Ex. 11.1.12].

79.9 Linearization

The local behavior of the dynamical system induced by a nonlinear differential equation can be studied via the linearization of the flow. At a fixed point of the nonlinear system the linearization is just a linear differential equation as studied in Sections 79.1 to 79.4. If the linearized system is hyperbolic, then the theorem of Hartman and Grobman states that the nonlinear flow is topologically conjugate to the linear flow. The invariant manifold theorem deals with those solutions of the nonlinear equation that are asymptotically attracted to (or repelled from) a fixed point. Basically these solutions live on manifolds that are described by nonlinear changes of coordinates of the linear stable (and unstable) subspaces.

Fact 4 below describes the simplest form of the invariant manifold theorem at a fixed point. It can be extended to include a "center manifold" (corresponding to the Lyapunov space with exponent 0). Furthermore, (local) invariant manifolds can be defined not just for the stable and unstable subspace, but for all Lyapunov spaces; see [BK94], [CK00], and [Rob98] for the necessary techniques and precise statements.

Both the Grobman–Hartman theorem as well as the invariant manifold theorem can be extended to time varying systems, i.e., to linear skew product flows as described in Sections 79.5 to 79.8. The general situation is discussed in [BK94], the case of linearization at a periodic solution is covered in [Rob98], random dynamical systems are treated in [Arn98], and robust systems (control systems) are the topic of [CK00].

Definitions:

A (nonlinear) **differential equation** in $\mathbb{R}^d$ is of the form $\dot{\mathbf{y}} = f(\mathbf{y})$, where f is a vector field on

$\mathbb{R}^d$. Assume that f is at least of class C^1 and that for all $\mathbf{y}_0 \in \mathbb{R}^d$ the solutions $\mathbf{y}(t, \mathbf{y}_0)$ of the initial value problem $\mathbf{y}(0, \mathbf{y}_0) = \mathbf{y}_0$ exist for all $t \in \mathbb{R}$.

A point $\mathbf{p} \in \mathbb{R}^d$ is a **fixed point** of the differential equation $\dot{\mathbf{y}} = f(\mathbf{y})$ if $\mathbf{y}(t, \mathbf{p}) = \mathbf{p}$ for all $t \in \mathbb{R}$.

The **linearization** of the equation $\dot{\mathbf{y}} = f(\mathbf{y})$ at a fixed point $\mathbf{p} \in \mathbb{R}^d$ is given by $\dot{\mathbf{x}} = D_{\mathbf{y}} f(\mathbf{p})\mathbf{x}$, where $D_{\mathbf{y}} f(\mathbf{p})$ is the Jacobian (matrix of partial derivatives) of f at the point $\mathbf{p}$.

A fixed point $\mathbf{p} \in \mathbb{R}^d$ of the differential equation $\dot{\mathbf{y}} = f(\mathbf{y})$ is called **hyperbolic** if $D_{\mathbf{y}} f(\mathbf{p})$ has no eigenvalues on the imaginary axis, i.e., if the matrix $D_{\mathbf{y}} f(\mathbf{p})$ is hyperbolic.

Consider a differential equation $\dot{\mathbf{y}} = f(\mathbf{y})$ in $\mathbb{R}^d$ with flow $\Phi : \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$, hyperbolic fixed point $\mathbf{p}$ and neighborhood $U(\mathbf{p})$. In this situation the **local stable manifold** and the **local unstable manifold** are defined as

$$W^s_{loc}(\mathbf{p}) = \{\mathbf{q} \in U\colon\ \lim\nolimits_{t\to\infty} \Phi(t, \mathbf{q}) = \mathbf{p}\} \text{ and } W^u_{loc}(\mathbf{p}) = \{\mathbf{q} \in U\colon\ \lim\nolimits_{t\to-\infty} \Phi(t, \mathbf{q}) = \mathbf{p}\},$$

respectively.

The local stable (and unstable) manifolds can be extended to **global invariant manifolds** by following the trajectories, i.e.,

$$W^s(\mathbf{p}) = \textstyle\bigcup_{t\geq 0} \Phi(-t, W^s_{loc}(\mathbf{p})) \text{ and } W^u(\mathbf{p}) = \textstyle\bigcup_{t\geq 0} \Phi(t, W^u_{loc}(\mathbf{p})).$$

Facts:

Literature: [Arn98], [AP90], [BK94], [CK00], [Rob98].

See Facts 79.2.3 and 79.2.4 for dynamical systems induced by differential equations and their fixed points.

1. (Hartman–Gobman) Consider a differential equation $\dot{\mathbf{y}} = f(\mathbf{y})$ in $\mathbb{R}^d$ with flow $\Phi : \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$. Assume that the equation has a hyperbolic fixed point $\mathbf{p}$ and denote the flow of the linearized equation $\dot{\mathbf{x}} = D_{\mathbf{y}} f(\mathbf{p})\mathbf{x}$ by $\Psi : \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$. Then there exist neighborhoods $U(\mathbf{p})$ of $\mathbf{p}$ and $V(\mathbf{0})$ of the origin in $\mathbb{R}^d$, and a homeomorphism $h : U(\mathbf{p}) \longrightarrow V(\mathbf{0})$ such that the flows $\Phi\ |_{U(\mathbf{p})}$ and $\Psi\ |_{V(\mathbf{0})}$ are (locally) C^0-conjugate, i.e., $h(\Phi(t, \mathbf{y})) = \Psi(t, h(\mathbf{y}))$ for all $\mathbf{y} \in U(\mathbf{p})$ and $t \in \mathbb{R}$ as long as the solutions stay within the respective neighborhoods.
2. Consider two differential equations $\dot{\mathbf{y}} = f_i(\mathbf{y})$ in $\mathbb{R}^d$ with flows $\Phi_i : \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$ for $i = 1, 2$. Assume that Φ_i has a hyperbolic fixed point $\mathbf{p}_i$ and the flows are C^k-conjugate for some $k \geq 1$ in neighborhoods of the $\mathbf{p}_i$. Then $\sigma(D_{\mathbf{y}} f_1(\mathbf{p}_1)) = \sigma(D_{\mathbf{y}} f_2(\mathbf{p}_2))$, i.e., the eigenvalues of the linearizations agree; compare Facts 79.2.6 and 79.2.7 for the linear situation.
3. Consider two differential equations $\dot{\mathbf{y}} = f_i(\mathbf{y})$ in $\mathbb{R}^d$ with flows $\Phi_i : \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$ for $i = 1, 2$. Assume that Φ_i has a hyperbolic fixed point $\mathbf{p}_i$ and the number of negative (or positive) Lyapunov exponents of $D_{\mathbf{y}} f_i(\mathbf{p}_i)$ agrees. Then the flows Φ_i are locally C^0-conjugate around the fixed points.
4. (Invariant Manifold Theorem) Consider a differential equation $\dot{\mathbf{y}} = f(\mathbf{y})$ in $\mathbb{R}^d$ with flow $\Phi : \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$. Assume that the equation has a hyperbolic fixed point p and denote the linearized equation by $\dot{\mathbf{x}} = D_{\mathbf{y}} f(p)\mathbf{x}$.
   - (i) There exists a neighborhood $U(\mathbf{p})$ in which the flow Φ has a local stable manifold $W^s_{loc}(\mathbf{p})$ and a local unstable manifold $W^u_{loc}(\mathbf{p})$.
   - (ii) Denote by L^- (and L^+) the stable (and unstable, respectively) subspace of $D_{\mathbf{y}} f(\mathbf{p})$; compare the definitions in Section 79.1. The dimensions of L^- (as a linear subspace of $\mathbb{R}^d$) and of $W^s_{loc}(\mathbf{p})$ (as a topological manifold) agree, similarly for L^+ and $W^u_{loc}(\mathbf{p})$.
   - (iii) The stable manifold $W^s_{loc}(\mathbf{p})$ is tangent to the stable subspace L^- at the fixed point $\mathbf{p}$, similarly for $W^u_{loc}(\mathbf{p})$ and L^+.

5. Consider a differential equation $\dot{\mathbf{y}} = f(\mathbf{y})$ in $\mathbb{R}^d$ with flow $\Phi : \mathbb{R} \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$. Assume that the equation has a hyperbolic fixed point $\mathbf{p}$. Then there exists a neighborhood $U(\mathbf{p})$ on which Φ is C^0-equivalent to the flow of a linear differential equation of the type

$$\begin{aligned} \dot{\mathbf{x}}_s &= -\mathbf{x}_s,\ \mathbf{x}_s \in \mathbb{R}^{d_s}, \\ \dot{\mathbf{x}}_u &= \mathbf{x}_u,\ \mathbf{x}_u \in \mathbb{R}^{d_u}, \end{aligned}$$

where d_s and d_u are the dimensions of the stable and the unstable subspace of $D_{\mathbf{y}} f(\mathbf{p})$, respectively, with $d_s + d_u = d$.

Examples:

1. Consider the nonlinear differential equation in $\mathbb{R}$ given by $\ddot{z} + z - z^3 = 0$, or in first-order form in $\mathbb{R}^2$
$$\begin{bmatrix} \dot{y}_1 \\ \dot{y}_2 \end{bmatrix} = \begin{bmatrix} y_2 \\ -y_1 + y_1^3 \end{bmatrix} = f(\mathbf{y}).$$
The fixed points of this system are $\mathbf{p}_1 = [0,0]^T$, $\mathbf{p}_2 = [1,0]^T$, $\mathbf{p}_3 = [-1,0]^T$. Computation of the linearization yields
$$D_{\mathbf{y}} f = \begin{bmatrix} 0 & 1 \\ -1 + 3y_1^2 & 0 \end{bmatrix}.$$
Hence, the fixed point $\mathbf{p}_1$ is not hyperbolic, while $\mathbf{p}_2$ and $\mathbf{p}_3$ have this property.
2. Consider the nonlinear differential equation in $\mathbb{R}$ given by $\ddot{z} + \sin(z) + \dot{z} = 0$, or in first-order form in $\mathbb{R}^2$
$$\begin{bmatrix} \dot{y}_1 \\ \dot{y}_2 \end{bmatrix} = \begin{bmatrix} y_2 \\ -\sin(y_1) - y_2 \end{bmatrix} = f(\mathbf{y}).$$
The fixed points of the system are $\mathbf{p}_n = [n\pi, 0]^T$ for $n \in \mathbb{Z}$. Computation of the linearization yields
$$D_{\mathbf{y}} f = \begin{bmatrix} 0 & 1 \\ -\cos(y_1) & -1 \end{bmatrix}.$$
Hence, for the fixed points $\mathbf{p}_n$ with n even the eigenvalues are $\mu_1, \mu_2 = -\frac{1}{2} \pm i\sqrt{\frac{3}{4}}$ with negative real part (or Lyapunov exponent), while at the fixed points $\mathbf{p}_n$ with n odd one obtains as eigenvalues $\nu_1, \nu_2 = -\frac{1}{2} \pm \sqrt{\frac{5}{4}}$, resulting in one positive and one negative eigenvalue. Hence, the flow of the differential equation is locally C^0-conjugate around all fixed points with even n, and around all fixed points with odd n, while the flows around, e.g., $\mathbf{p}_0$ and $\mathbf{p}_1$ are not conjugate.

Given a dynamical system described by the ordinary differential equation (ODE)

$$\dot{\mathbf{x}}(t) = \mathbf{f}(t, \mathbf{x}(t), \mathbf{u}(t)), \ \mathbf{x}(t_0) = \mathbf{x}^0,$$

where $\mathbf{x}$ is the state of the system and $\mathbf{u}$ serves as input, the major problem in control theory is to steer the state from $\mathbf{x}^0$ to some desired state; i.e., for a given initial value $\mathbf{x}(t_0) = \mathbf{x}^0$ and target $\mathbf{x}^1$, can we find a piecewise continuous or L_2 (i.e., square-integrable, Lebesgue measurable) control function $\hat{\mathbf{u}}$ such that there exists $t_1 \geq t_0$ with $\mathbf{x}(t_1; \hat{\mathbf{u}}) = \mathbf{x}^1$, where $\mathbf{x}(t; \hat{\mathbf{u}})$ is the solution trajectory of the ODE given above for $\mathbf{u} \equiv \hat{\mathbf{u}}$? Often, the target is $\mathbf{x}^1 = 0$, in particular if $\mathbf{x}$ describes the deviation from a nominal path. A weaker demand is to asymptotically stabilize the system, i.e., to find an admissible control function $\hat{\mathbf{u}}$ (i.e., a piecewise continuous or L_2 function $\hat{\mathbf{u}} : [t_0, t_1] \mapsto \mathcal{U}$) such that $\lim_{t\to\infty} \mathbf{x}(t; \hat{\mathbf{u}}) = 0$).

Another major problem in control theory arises from the fact that often, not all states are available for measurements or observations. Thus, we are faced with the question: Given partial information about the states, is it possible to reconstruct the solution trajectory from the measurements/observations? If this is the case, the states can be estimated by state observers. The classical approach leads to the Luenberger observer, but nowadays most frequently the famous Kalman–Bucy filter [KB61] is used as it can be considered as an optimal state observer in a least-squares sense and allows for stochastic uncertainties in the system.

Analyzing the above questions concerning controllability, observability, etc. for general control systems is beyond the scope of linear algebra. Therefore, we will mostly focus on linear time-invariant (LTI) systems that can be analyzed with tools relying on linear algebra techniques. (For further reading, see, e.g., [Lev96], [Mut99], and [Son98].)

Once the above questions are settled, it is interesting to ask how the desired control objectives can be achieved in an optimal way. The linear-quadratic regulator (LQR) problem is equivalent to a dynamic optimization problem for linear differential equations. Its significance for control theory was fully discovered first by Kalman in 1960 [Kal60]. One of its main applications is to steer the solution of the underlying linear differential equation to a desired reference trajectory with minimal cost given full information on the states. If full information is not available, then the states can be estimated from the measurements or observations using a Kalman–Bucy filter. This leads to the linear-quadratic Gaussian (LQG) control problem. The latter problem and its solution were first described in the classical papers [Kal60] and [KB61] and are nowadays contained in any textbook on control theory.

In the past decades, the interest has shifted from optimal control to robust control. The question raised is whether a given control law is still able to achieve a desired performance in the presence of uncertain disturbances. In this sense, the LQR control law has some robustness, while the LQG design cannot be considered to be robust [Doy78]. The H_∞ control problem aims at minimizing the worst-case error that can occur if the system is perturbed by exogenous perturbations. It is, thus, one example of a *robust control* problem. We will only introduce the standard H_∞ control problem, though there exist many other robust control problems and several variations of the H_∞ control problem; see [GL95], [PUA00], [ZDG96].

Many of the above questions lead to methods that involve the solution of linear and nonlinear matrix equations, in particular Lyapunov, Sylvester, and Riccati equations. For instance, stability, controllability, and observability of LTI systems can be related to solutions of Lyapunov equations (see, e.g., [LT85, Sect. 13] and [HJ91]), while the LQR, LQG, and H_∞ control problems lead to the solution of algebraic Riccati equations (see, e.g., [AKF$^+$03], [Dat04], [LR95], [Meh91], and [Sim96]). Therefore, we will provide the most relevant properties of these matrix equations. (See also Chapter 19 for more classes of matrix equations.)

The concepts and solution techniques contained in this chapter and many other control-related algorithms are implemented in the MATLAB® Control System Toolbox, the Subroutine Library in Control SLICOT [BMS$^+$99], and many other computer-aided control systems design tools.

Finally, we note that all concepts described in this section are related to *continuous-time* systems. Analogous concepts hold for *discrete-time systems* whose dynamics are described by difference equations; see, e.g., [Kuc91].

80.1 Basic Concepts

Definitions:

Given sets $\mathcal{X}$ (the **state space**), $\mathcal{U}$ (the **input space**), and $\mathcal{Y}$ (the **output space**) and measurable functions $\mathbf{f}, \mathbf{g} : [t_0, t_f] \times \mathcal{X} \times \mathcal{U} \mapsto \mathbb{R}^n$, a **control system** is defined by

$$\dot{\mathbf{x}}(t) = \mathbf{f}(t, \mathbf{x}(t), \mathbf{u}(t)),$$

$$\mathbf{y}(t) = \mathbf{g}(t, \mathbf{x}(t), \mathbf{u}(t)),$$

where the differential equation is called the **state equation**, the second equation is called the **observer equation**, and $t \in [t_0, t_f]$ ($t_f \in [0, \infty]$).

Here,

$$\mathbf{x} : [t_0, t_f] \mapsto \mathcal{X} \text{ is the } \textbf{state (vector)},$$

$$\mathbf{u} : [t_0, t_f] \mapsto \mathcal{U} \text{ is the } \textbf{control (vector)},$$

$$\mathbf{y} : [t_0, t_f] \mapsto \mathcal{Y} \text{ is the } \textbf{output (vector)}.$$

A control system is called **autonomous** (**time-invariant**) if

$$\mathbf{f}(t, \mathbf{x}, \mathbf{u}) \equiv \mathbf{f}(\mathbf{x}, \mathbf{u}) \text{ and } \mathbf{g}(t, \mathbf{x}, \mathbf{u}) \equiv \mathbf{g}(\mathbf{x}, \mathbf{u}).$$

The number of state-space variables n is called the **order** or **degree** of the system.

Let $\mathbf{x}^1 \in \mathcal{X}$. A control system with initial value $\mathbf{x}(t_0) = \mathbf{x}^0$ is **controllable to $\mathbf{x}^1$ in time** $t_1 > t_0$ if there exists an **admissible** control function $\mathbf{u}$ (i.e., a piecewise continuous or L_2 function $\mathbf{u} : [t_0, t_1] \mapsto \mathcal{U}$) such that $\mathbf{x}(t_1; \mathbf{u}) = \mathbf{x}^1$. (Equivalently, $(t_1, \mathbf{x}^1)$ is **reachable from** $(t_0, \mathbf{x}^0)$.)

A control system with initial value $\mathbf{x}(t_0) = \mathbf{x}^0$ is **controllable to $\mathbf{x}^1$** if there exists $t_1 > t_0$ such that $(t_1, \mathbf{x}^1)$ is reachable from $(t_0, \mathbf{x}^0)$.

If the control system is controllable to all $\mathbf{x}^1 \in \mathcal{X}$ for all $(t_0, \mathbf{x}^0)$ with $\mathbf{x}^0 \in \mathcal{X}$, it is **(completely) controllable.**

A control system is **linear** if $\mathcal{X} = \mathbb{R}^n$, $\mathcal{U} = \mathbb{R}^m$, $\mathcal{Y} = \mathbb{R}^p$, and

$$\mathbf{f}(t, \mathbf{x}, \mathbf{u}) = A(t)\mathbf{x}(t) + B(t)\mathbf{u}(t),$$
$$\mathbf{g}(t, \mathbf{x}, \mathbf{u}) = C(t)\mathbf{x}(t) + D(t)\mathbf{u}(t),$$

where $A : [t_0, t_f] \mapsto \mathbb{R}^{n\times n}, B : [t_0, t_f] \mapsto \mathbb{R}^{n\times m}, C : [t_0, t_f] \mapsto \mathbb{R}^{p\times n}, D : [t_0, t_f] \mapsto \mathbb{R}^{p\times m}$ are smooth functions.

A linear **time-invariant system** (**LTI system**) has the form

$$\begin{aligned} \dot{\mathbf{x}}(t) &= A\mathbf{x}(t) + B\mathbf{u}(t), \\ \mathbf{y}(t) &= C\mathbf{x}(t) + D\mathbf{u}(t), \end{aligned}$$

with $A \in \mathbb{R}^{n\times n}$, $B \in \mathbb{R}^{n\times m}$, $C \in \mathbb{R}^{p\times n}$, and $D \in \mathbb{R}^{p\times m}$.

An LTI system is **(asymptotically) stable** if the corresponding linear homogeneous ODE $\dot{\mathbf{x}} = A\mathbf{x}$ is (asymptotically) stable. (For a definition of (asymptotic) stability confer Chapter 78 and Chapter 79.)

An LTI system is **stabilizable (by state feedback)** if there exists an admissible control in the form of a **state feedback**

$$\mathbf{u}(t) = F\mathbf{x}(t), \quad F \in \mathbb{R}^{m\times n},$$

such that the unique solution of the corresponding **closed-loop** ODE

$$\dot{\mathbf{x}}(t) = (A + BF)\mathbf{x}(t) \tag{80.1}$$

is asymptotically stable.

An LTI system is **observable (reconstructible)** if for two solution trajectories $\mathbf{x}(t)$ and $\tilde{\mathbf{x}}(t)$ of its state equation, it holds that

$$C\mathbf{x}(t) = C\tilde{\mathbf{x}}(t) \quad \forall t \le t_0 \ (\forall t \ge t_0)$$

implies $\mathbf{x}(t) = \tilde{\mathbf{x}}(t) \quad \forall t \le t_0 \ (\forall t \ge t_0)$.

An LTI system is **detectable** if for any solution $\mathbf{x}(t)$ of $\dot{\mathbf{x}} = A\mathbf{x}$ with $C\mathbf{x}(t) \equiv 0$ we have $\lim_{t\to\infty} \mathbf{x}(t) = 0$.

Facts:

1. For LTI systems, all controllability and reachability concepts are equivalent. Therefore, we only speak of controllability of LTI systems.
2. Observability implies that one can obtain all necessary information about the LTI system from the output equation.
3. Detectability weakens observability in the same sense as stabilizability weakens controllability: Not all of $\mathbf{x}$ can be observed, but the unobservable part is asymptotically stable.
4. Observability (detectability) and controllability (stabilizability) are dual concepts in the following sense: an LTI system is observable if and only if the dual system

$$\dot{\mathbf{z}}(t) = -A^T\mathbf{z}(t) - C^T\mathbf{v}(t)$$

is controllable. An LTI system is detectable if and only if (A^T, C^T) defines a stabilizable system. These facts are sometimes called *duality principle of control theory.*

Examples:

1. A fundamental problem in robotics is to control the position of a single-link rotational joint using a motor placed at the "pivot." A simple mathematical model for this is the pendulum [Son98]. Applying a torque $\mathbf{u}$ as external force, this can serve as a means to control the motion of the pendulum (Figure 80.1).

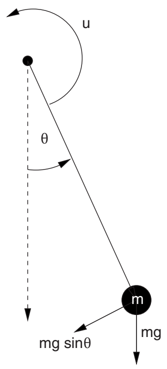

FIGURE 80.1 Pendulum as a mathematical model of a single-link rotational joint.

If we neglect friction and assume that the mass is concentrated at the tip of the pendulum, Newton's law for rotating objects

$$m\ddot{\Theta}(t) + mg\sin\Theta(t) = \mathbf{u}(t)$$

describes the counterclockwise movement of the angle between the vertical axis and the pendulum subject to the control $\mathbf{u}(t)$. This is a first example of a (nonlinear) control system if we set

$$\mathbf{x}(t) = \begin{bmatrix} x_1(t) \\ x_2(t) \end{bmatrix} = \begin{bmatrix} \Theta(t) \\ \dot{\Theta}(t) \end{bmatrix},$$

$$\mathbf{f}(t,\mathbf{x},\mathbf{u}) = \begin{bmatrix} x_2 \\ -mg\sin(x_1) \end{bmatrix}, \quad \mathbf{g}(t,\mathbf{x},\mathbf{u}) = x_1,$$

where we assume that only $\Theta(t)$ can be measured, but not the angular velocity $\dot{\Theta}(t)$.

For $\mathbf{u}(t) \equiv 0$, the stationary position $\Theta = \pi, \dot{\Theta} = 0$ is an unstable equilibrium, i.e., small perturbations will lead to unstable motion. The objective now is to apply a torque (control $\mathbf{u}$) to correct for deviations from this unstable equilibrium, i.e., to keep the pendulum in the upright position (Figure 80.2).

2. Scaling the variables such that $m = 1 = g$ and assuming a small perturbation $\Theta - \pi$ in the inverted pendulum problem described above, we have

$$\sin\Theta = -(\Theta - \pi) + o((\Theta - \pi)^2).$$

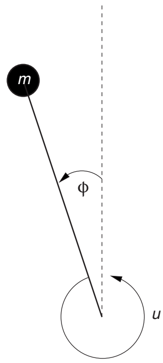

FIGURE 80.2 Inverted pendulum; apply control to move to upright position.

(Here, $\mathbf{g}(x) = o(x)$ if $\lim\limits_{x\to\infty} \frac{\mathbf{g}(x)}{x} = 0$.) This allows us to linearize the control system in order to obtain a linear control system for $\varphi(t) := \Theta(t) - \pi$:

$$\ddot{\varphi}(t) - \varphi(t) = \mathbf{u}(t).$$

This can be written as an LTI system, assuming only positions can be observed, with

$$\mathbf{x} = \begin{bmatrix} \varphi \\ \dot{\varphi} \end{bmatrix}, \quad A = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}, \quad C = \begin{bmatrix} 1 & 0 \end{bmatrix}, \quad D = 0.$$

Now the objective translates to: Given initial values $x_1(0) = \varphi(0)$, $x_2(0) = \dot{\varphi}(0)$, find $\mathbf{u}(t)$ to bring $\mathbf{x}(t)$ to zero "as fast as possible." It is usually an additional goal to avoid overshoot and oscillating behavior as much as possible.

80.2 Frequency-Domain Analysis

Thus far, LTI systems are treated in state space. In systems and control theory, it is often beneficial to use the *frequency domain* formalism obtained from applying the Laplace transformation to its state and observer equations.

Definitions:

The rational matrix function

$$G(s) = C(sI - A)^{-1}B + D \in \mathbb{R}^{p\times m}[s]$$

is called the **transfer function** of the LTI system defined in Section 80.1.

In a **frequency domain analysis**, $G(s)$ is evaluated for $s = i\omega$, where $\omega \in [0, \infty]$ has the physical interpretation of a frequency and the input is considered as a signal with frequency ω.

The L_∞**-norm** of a transfer function is the operator norm induced by the frequency domain analogue of the L_2-norm that applies to Laplace transformed input functions $\mathbf{u} \in L_2(-\infty, \infty; \mathbb{R}^m)$, where $L_2(a, b; \mathbb{R}^m)$ is the Lebesgue space of square-integrable, measurable functions on the interval $(a, b) \subset \mathbb{R}$ with values in $\mathbb{R}^m$.

The $p \times m$-matrix-valued functions G for which $\|G\|_{L_\infty}$ is bounded form the space L_∞.

The subset of L_∞ containing all $p \times m$-matrix-valued functions that are analytical and bounded in the open right-half complex plane form the **Hardy space** H_∞.

The H_∞**-norm** of $G \in H_\infty$ is defined as

$$\|G\|_{H_\infty} = \operatorname*{ess\,sup}_{\omega\in\mathbb{R}} \sigma_{\max}(G(i\omega)), \tag{80.2}$$

where $\sigma_{\max}(M)$ is the maximum singular value of the matrix M and ess $\sup_{t\in M} h(t)$ is the essential supremum of a function h evaluated on the set M, which is the function's supremum on $M \setminus L$ where L is a set of Lebesgue measure zero.

For $T \in \mathbb{R}^{n\times n}$ nonsingular, the mapping implied by

$$(A, B, C, D) \mapsto (TAT^{-1}, TB, CT^{-1}, D)$$

is called a **state-space transformation**.

(A, B, C, D) is called a **realization** of an LTI system if its transfer function can be expressed as $G(s) = C(sI_n - A)^{-1}B + D$.

The minimum number $\hat{n}$ so that there exists no realization of a given LTI system with $n < \hat{n}$ is called the **McMillan degree** of the system.

A realization with $n = \hat{n}$ is a **minimal realization**.

Facts:

1. If $\mathbf{X}, \mathbf{Y}, \mathbf{U}$ are the Laplace transforms of $\mathbf{x}, \mathbf{y}, \mathbf{u}$, respectively, s is the Laplace variable, and $\mathbf{x}(0) = 0$, the state and observer equation of an LTI system transform to

$$\begin{aligned} s\mathbf{X}(s) &= A\mathbf{X}(s) + B\mathbf{U}(s), \\ \mathbf{Y}(s) &= C\mathbf{X}(s) + D\mathbf{U}(s). \end{aligned}$$

   Thus, the resulting input–output relation

$$\mathbf{Y}(s) = \big(C(sI - A)^{-1}B + D\big)\,\mathbf{U}(s) = G(s)\mathbf{U}(s) \tag{80.3}$$

   is completely determined by the transfer function of the LTI system.
2. As a consequence of the maximum modulus theorem, H_∞ functions must be bounded on the imaginary axis so that the essential supremum in the definition of the H_∞-norm simplifies to a supremum for rational functions G.
3. The transfer function of an LTI system is invariant w.r.t. state-space transformations:

$$D + (CT^{-1})(sI - TAT^{-1})^{-1}(TB) = C(sI_n - A)^{-1}B + D = G(s).$$

   Consequently, there exist infinitely many realizations of an LTI system.
4. Adding zero inputs/outputs does not change the transfer function; thus, the order n of the system can be increased arbitrarily.

Examples:

1. The LTI system corresponding to the inverted pendulum has the transfer function

$$G(s) = \begin{bmatrix} 1 & 0 \end{bmatrix} \begin{bmatrix} s & -1 \\ -1 & s \end{bmatrix}^{-1} \begin{bmatrix} 0 \\ 1 \end{bmatrix} + [0] = \frac{1}{s^2 - 1}.$$

2. The L_∞-norm of the transfer function corresponding to the inverted pendulum is

$$\|G\|_{L_\infty} = 1.$$

3. The transfer function corresponding to the inverted pendulum is not in H_∞ as $G(s)$ has a pole at $s = 1$ and, thus, is not bounded in the right-half plane.

80.3 Analysis of LTI Systems

In this section, we provide characterizations of the properties of LTI systems defined in the introduction. Controllability and the related concepts can be checked using several algebraic criteria.

Definitions:

A matrix $A \in \mathbb{R}^{n\times n}$ is **Hurwitz** or **(asymptotically) stable** if all its eigenvalues have strictly negative real part.

The **controllability matrix** corresponding to an LTI system is

$$\mathcal{C}(A,B) = [B, AB, A^2B, \ldots, A^{n-1}B] \in \mathbb{R}^{n\times n\cdot m}.$$

The **observability matrix** corresponding to an LTI system is

$$\mathcal{O}(A,C) = \begin{bmatrix} C \\ CA \\ CA^2 \\ \vdots \\ CA^{n-1} \end{bmatrix} \in \mathbb{R}^{np\times n}.$$

The following transformations are **state-space transformations:**

- **Change of basis:**

$$\begin{array}{llll} \mathbf{x} \mapsto P\mathbf{x} & \text{for} & P \in \mathbb{R}^{n\times n} & \text{nonsingular,} \\ \mathbf{u} \mapsto Q\mathbf{u} & \text{for} & Q \in \mathbb{R}^{m\times m} & \text{nonsingular,} \\ \mathbf{y} \mapsto R\mathbf{y} & \text{for} & R \in \mathbb{R}^{p\times p} & \text{nonsingular.} \end{array}$$

- **Linear state feedback:** $\mathbf{u} \mapsto F\mathbf{x} + \mathbf{v}, F \in \mathbb{R}^{m\times n}$, $\mathbf{v} : [t_0, t_f] \mapsto \mathbb{R}^m$.
- **Linear output feedback:** $\mathbf{u} \mapsto G\mathbf{y} + \mathbf{v}, G \in \mathbb{R}^{m+p}$, $\mathbf{v} : [t_0, t_f] \mapsto \mathbb{R}^m$.

The **(controllability) Kalman decomposition** of (A, B) is

$$V^TAV = \begin{bmatrix} A_1 & A_2 \\ 0 & A_3 \end{bmatrix}, \quad V^TB = \begin{bmatrix} B_1 \\ 0 \end{bmatrix}, \quad V \ \in \mathbb{R}^{n\times n} \text{ orthogonal,}$$

where (A_1, B_1) is controllable.

The **observability Kalman decomposition** of (A, C) is

$$W^TAW = \begin{bmatrix} A_1 & 0 \\ A_2 & A_3 \end{bmatrix}, \quad CW = [C_1 \ 0], \quad W \ \in \mathbb{R}^{n\times n} \text{ orthogonal,}$$

where (A_1, C_1) is observable.

Facts:

1. An LTI system is asymptotically stable if and only if A is Hurwitz.
2. For a given LTI system, the following are equivalent.
   (a) The LTI system is controllable.
   (b) The controllability matrix corresponding to the LTI system has full (row) rank, i.e., $\operatorname{rank} \mathcal{C}(A, B) = n$.

   (c) (*Hautus–Popov test*) If $\mathbf{p} \neq 0$ and $\mathbf{p}^* A = \lambda \mathbf{p}^*$, then $\mathbf{p}^* B \neq 0$.
   (d) $\mathrm{rank}([\lambda I - A, B]) = n \ \forall \lambda \in \mathbb{C}$.

   The essential part of the proof of the above characterizations (which is "d)⇒b)") is an application of the Cayley–Hamilton theorem (Section 4.4).

3. For a given LTI system, the following are equivalent:
   (a) The LTI system is stabilizable, i.e., $\exists F \in \mathbb{R}^{m \times n}$ such that $A + BF$ is Hurwitz.
   (b) (*Hautus–Popov test*) If $\mathbf{p} \neq 0$, $\mathbf{p}^* A = \lambda \mathbf{p}^*$, and $\mathrm{Re}(\lambda) \geq 0$, then $\mathbf{p}^* B \neq 0$.
   (c) $\mathrm{rank}([A - \lambda I, B]) = n, \quad \forall \lambda \in \mathbb{C}$ with $\mathrm{Re}(\lambda) \geq 0$.
   (d) In the Kalman decomposition of (A, B), A_3 is Hurwitz.
4. Using the change of basis $\tilde{\mathbf{x}} = V^T \mathbf{x}$ implied by the Kalman decomposition, we obtain

$$\begin{aligned} \dot{\tilde{\mathbf{x}}}_1 &= A_1 \tilde{\mathbf{x}}_1 + A_2 \tilde{\mathbf{x}}_2 + B_1 \mathbf{u}, \\ \dot{\tilde{\mathbf{x}}}_2 &= A_3 \tilde{\mathbf{x}}_2. \end{aligned}$$

   Thus, $\tilde{\mathbf{x}}_2$ is not controllable. The eigenvectors of A corresponding to the eigenvalues of A_3 (which form a subset of the eigenvalues of A) are, therefore, called *uncontrollable modes*.
5. For a given LTI system, the following are equivalent:
   (a) The LTI system is observable.
   (b) The observability matrix corresponding to the LTI system has full (column) rank, i.e., $\mathrm{rank}\, \mathcal{O}(A, C) = n$.
   (c) (*Hautus–Popov test*) $\mathbf{p} \neq 0$, $A\mathbf{p} = \lambda \mathbf{p} \Longrightarrow C\mathbf{p} \neq 0$.
   (d) $\mathrm{rank} \begin{bmatrix} \lambda I - A \\ C \end{bmatrix} = n, \quad \forall \lambda \in \mathbb{C}$.
6. For a given LTI system, the following are equivalent:
   (a) The LTI system is detectable.
   (b) The matrix pair (A^T, C^T) defines a stabilizable system.
   (c) (*Hautus–Popov test*) $\mathbf{p} \neq 0$, $A\mathbf{p} = \lambda \mathbf{p}, \mathrm{Re}(\lambda) \geq 0 \Longrightarrow C\mathbf{p} \neq 0$.
   (d) $\mathrm{rank} \begin{bmatrix} \lambda I - A \\ C \end{bmatrix} = n, \quad \forall \lambda \in \mathbb{C}$ with $\mathrm{Re}(\lambda) \geq 0$.
   (e) In the observability Kalman decomposition of (A, C), A_3 is Hurwitz.
7. Using the change of basis $\tilde{\mathbf{x}} = W^T \mathbf{x}$ implied by the observability Kalman decomposition we obtain

$$\begin{aligned} \dot{\tilde{\mathbf{x}}}_1 &= A_1 \tilde{\mathbf{x}}_1 + B_1 \mathbf{u}, \\ \tilde{\mathbf{x}}_2 &= A_2 \tilde{\mathbf{x}}_1 + A_3 \tilde{\mathbf{x}}_2 + B_2 \mathbf{u}, \\ \mathbf{y} &= C_1 \tilde{\mathbf{x}}_1. \end{aligned}$$

   Thus, $\tilde{\mathbf{x}}_2$ is not observable. The eigenvectors of A corresponding to the eigenvalues of A_3 (which form a subset of the eigenvalues of A) are, therefore, called *unobservable modes*.
8. The characterizations of observability and detectability are proved using the duality principle and the characterizations of controllability and stabilizability.
9. If an LTI system is controllable (observable, stabilizable, detectable), then the corresponding LTI system resulting from a state-space transformation is controllable (observable, stabilizable, detectable).

10. For $A \in \mathbb{R}^{n\times n}, B \in \mathbb{R}^{n\times m}$ there exist $P \in \mathbb{R}^{n\times n}, Q \in \mathbb{R}^{m\times m}$ orthogonal such that

$$PAP^T = \begin{array}{cc} \left[\begin{array}{ccccc|c} A_{11} & & & & A_{1,s-1} & A_{1,s} \\ A_{21} & \ddots & & & \vdots & \vdots \\ 0 & \ddots & \ddots & & \vdots & \vdots \\ \vdots & \ddots & & & & \\ 0 & \cdots & 0 & A_{s-1,s-2} & A_{s-1,s-1} & A_{s-1,s} \\ 0 & \cdots & 0 & 0 & 0 & A_{ss} \end{array}\right] & \begin{array}{c} n_1 \\ n_2 \\ \\ \\ n_{s-1} \\ n_s \end{array} \\ \begin{array}{cccccc} n_1 & & & n_{s-2} & n_{s-1} & n_s \end{array} & \end{array},$$

$$PBQ = \begin{array}{cc} \left[\begin{array}{cc} B_1 & 0 \\ 0 & 0 \\ \vdots & \vdots \\ 0 & 0 \end{array}\right] & \begin{array}{c} n_1 \\ n_2 \\ \vdots \\ n_s \end{array} \\ \begin{array}{cc} n_1 & m-n_1 \end{array} & \end{array},$$

where $n_1 \geq n_2 \geq \ldots \geq n_{s-1} \geq n_s \geq 0$, $n_{s-1} > 0$, $A_{i,i-1} = [\Sigma_{i,i-1}\ 0] \in \mathbb{R}^{n_1\times n_{i-1}}$, $\Sigma_{i,i-1} \in \mathbb{R}^{n_i\times n_i}$ nonsingular for $i = 1, \ldots, s-1$, $\Sigma_{s-1,s-2}$ is diagonal, and B_1 is nonsingular.

   Moreover, this transformation to *staircase form* can be computed by a finite sequence of singular value decompositions.
11. An LTI system is controllable if in the staircase form of (A, B), $n_s = 0$.
12. An LTI system is observable if $n_s = 0$ in the staircase form of (A^T, C^T).
13. An LTI system is stabilizable if in the staircase form of (A, B), A_{ss} is Hurwitz.
14. An LTI system is detectable if in the staircase form of (A^T, C^T), A_{ss} is Hurwitz.
15. In case $m = 1$, the staircase form of (A, B) is given by

$$PAP^T = \begin{bmatrix} a_{11} & \cdots & \cdots & a_{1,n} \\ a_{21} & a_{22} & & \vdots \\ & \ddots & \ddots & \vdots \\ & & a_{n,n-1} & a_{n,n} \end{bmatrix}, \ PB = \begin{bmatrix} b_1 \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

   and is called the *controllability Hessenberg form.* The corresponding staircase from of (A^T, C^T) in case $p = 1$ is called the *observability Hessenberg form.*

Examples:

1. The LTI system corresponding to the inverted pendulum problem is not asymptotically stable as A is not Hurwitz: $\sigma(A) = \{\pm 1\}$.
2. The LTI system corresponding to the inverted pendulum problem is controllable as the controllability matrix

$$\mathcal{C}(A, B) = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

   has full rank. Thus, it is also stabilizable.

3. The LTI system corresponding to the inverted pendulum problem is observable as the observability matrix
$$\mathcal{O}(A, C) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$$
has full rank. Thus, it is also detectable.

80.4 Matrix Equations

A fundamental role in many tasks in control theory is played by matrix equations. We, therefore, review their most important properties. More details can be found in [AKF$^+$03], [BIM12], [HJ91], [LR95], and [LT85]; see also Chapter 19.

Definitions:

A linear matrix equation of the form
$$AX + XB = W, \qquad A \in \mathbb{R}^{n\times n}, B \in \mathbb{R}^{m\times m}, W \in \mathbb{R}^{n\times m},$$
is called a **Sylvester equation**.

A linear matrix equation of the form
$$AX + XA^T = W, \qquad A \in \mathbb{R}^{n\times n}, W = W^T \in \mathbb{R}^{n\times n},$$
is called a **Lyapunov equation**.

A quadratic matrix equation of the form
$$0 = Q + A^T X + XA - XGX, \qquad A \in \mathbb{R}^{n\times n}, G = G^T, Q = Q^T \in \mathbb{R}^{n\times n},$$
is called an **algebraic Riccati equation (ARE)**.

Facts:

1. The Sylvester equation is equivalent to the linear system of equations
$$\left[(I_m \otimes A) + (B^T \otimes I_n)\right] \operatorname{vec}(X) = \operatorname{vec}(W),$$
where $\otimes$ and vec denote the Kronecker product and the vec-operator defined in Section 11.4. Thus, the Sylvester equation has a unique solution if and only if $\sigma(A) \cap \sigma(-B) = \emptyset$.
2. The Lyapunov equation is equivalent to the linear system of equations
$$[(I_m \otimes A) + (A \otimes I_n)] \operatorname{vec}(X) = \operatorname{vec}(W).$$
Thus, it has a unique solution if and only if $\sigma(A) \cap \sigma(-A^T) = \emptyset$. In particular, this holds if A is Hurwitz.
3. If G and Q are positive semidefinite with (A, G) stabilizable and (A, Q) detectable, then the ARE has a unique positive semidefinite solution X_* with the property that $\sigma(A - GX_*)$ is Hurwitz.
4. If the assumptions given above are not satisfied, there may or may not exist a stabilizing solution with the given properties. Besides, there may exist a continuum of solutions, a finite number of solutions, or no solution at all. The solution theory for AREs is a vast topic by itself; see the monographs [AKF$^+$03], [LR95], and [BIM12], [Ben99], [BLP08], [Dat04], [Meh91], and [Sim96] for numerical algorithms to solve these equations.

Examples:

1. For
$$A = \begin{bmatrix} 1 & 2 \\ 0 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 2 & -1 \\ 1 & 0 \end{bmatrix}, \quad W = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix},$$
a solution of the Sylvester equation is
$$X = \frac{1}{4}\begin{bmatrix} -3 & 3 \\ 1 & -3 \end{bmatrix}.$$
Note that $\sigma(A) = \sigma(B) = \{1, 1\}$ so that $\sigma(A) \cap \sigma(-B) = \emptyset$. Thus, this Sylvester equation has the unique solution X given above.
2. For
$$A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \quad G = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}, \quad Q = \begin{bmatrix} 1 & 0 \\ 0 & 2 \end{bmatrix},$$
the stabilizing solution of the associated ARE is
$$X_* = \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix}$$
and the spectrum of the closed-loop matrix
$$A - GX_* = \begin{bmatrix} 0 & 1 \\ -1 & -2 \end{bmatrix}$$
is $\{-1, \ -1\}$.
3. Consider the ARE
$$0 = C^T C + A^T X + XA - XBB^T X$$
corresponding to an LTI system with
$$A = \begin{bmatrix} -1 & 0 \\ 0 & 0 \end{bmatrix}, \quad B = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \quad C = \begin{bmatrix} \sqrt{2} & 0 \end{bmatrix}, \quad D = 0.$$
For this ARE, $X = \begin{bmatrix} -1+\sqrt{3} & 0 \\ 0 & \xi \end{bmatrix}$ is a solution for all $\xi \in \mathbb{R}$. It is positive semidefinite for all $\xi \geq 0$, but this ARE does not have a stabilizing solution as the LTI system is neither stabilizable nor detectable.

80.5 State Estimation

In this section, we present the two most famous approaches to state observation, that is, finding a function $\hat{\mathbf{x}}(t)$ that approximates the state $\mathbf{x}(t)$ of a given LTI system if only its inputs $\mathbf{u}(t)$ and outputs $\mathbf{y}(t)$ are known. While the first approach (the Luenberger observer) assumes a deterministic system behavior, the Kalman–Bucy filter allows for uncertainty in the system, modeled by white-noise, zero-mean stochastic processes.

Definitions:

Given an LTI system with $D = 0$, a **state observer** is a function
$$\hat{\mathbf{x}} : [0, \infty) \mapsto \mathbb{R}^n$$

such that for some nonsingular matrix $Z \in \mathbb{R}^{n\times n}$ and $\mathbf{e}(t) = \hat{\mathbf{x}}(t) - Z\mathbf{x}(t)$, we have

$$\lim_{t\to\infty} \mathbf{e}(t) = 0.$$

Given an LTI system with stochastic disturbances

$$\begin{aligned} \dot{\mathbf{x}}(t) &= A\mathbf{x}(t) + B\mathbf{u}(t) + \tilde{B}\mathbf{w}(t), \\ \mathbf{y}(t) &= C\mathbf{x}(t) + \mathbf{v}(t), \end{aligned}$$

where A, B, C are as before, $\tilde{B} \in \mathbb{R}^{n\times\tilde{m}}$, and $\mathbf{w}(t), \mathbf{v}(t)$ are white-noise, zero-mean stochastic processes with corresponding covariance matrices $W = W^T \in \mathbb{R}^{\tilde{m}\times\tilde{m}}$ (positive semidefinite), $V = V^T \in \mathbb{R}^{p\times p}$ (positive definite), the problem to minimize the mean square error

$$E\left[\|\mathbf{x}(t) - \hat{\mathbf{x}}(t)\|_2^2\right]$$

over all state observers is called the **optimal estimation problem**. (Here, $E[r]$ is the **expected value** of r.)

Facts:

1. A state observer, called the *Luenberger observer*, is obtained as the solution of the dynamical system
$$\dot{\hat{\mathbf{x}}}(t) = H\hat{\mathbf{x}}(t) + F\mathbf{y}(t) + G\mathbf{u}(t),$$
where $H \in \mathbb{R}^{n\times n}$ and $F \in \mathbb{R}^{n\times p}$ are chosen so that H is Hurwitz and the *Sylvester observer equation*
$$HX - XA + FC = 0$$
has a nonsingular solution X. Then $G = XB$ and the matrix Z in the definition of the state observer equals the solution X of the Sylvester observer equation.
2. Assuming that
   (a) $\mathbf{w}$ and $\mathbf{v}$ are uncorrelated stochastic processes,
   (b) the initial state $\mathbf{x}^0$ is a Gaussian zero-mean random variable, uncorrelated to $\mathbf{w}$ and $\mathbf{v}$,
   (c) (A, B) is controllable and (A, C) is observable,

   the solution to the optimal estimation problem is given by the *Kalman–Bucy* filter, defined as the solution of the linear differential equation
$$\dot{\hat{\mathbf{x}}}(t) = (A - Y_* C^T V^{-1} C)\hat{\mathbf{x}}(t) + B\mathbf{u}(t) + Y_* C^T V^{-1}\mathbf{y}(t),$$
where Y_* is the unique stabilizing solution of the *filter ARE:*
$$0 = \tilde{B}W\tilde{B}^T + AY + YA^T - YC^TV^{-1}CY.$$
3. Under the same assumptions as above, the stabilizing solution of the filter ARE can be shown to be symmetric positive definite.

Examples:

1. A Luenberger observer for the LTI system corresponding to the inverted pendulum problem can be constructed as follows: Choose $H = \operatorname{diag}(-2, -\frac{1}{2})$ and $F = \begin{bmatrix} 2 & 1 \end{bmatrix}^T$. Then the Sylvester observer equation has the unique solution
$$X = \frac{1}{3}\begin{bmatrix} 4 & -2 \\ -2 & 4 \end{bmatrix}.$$
Note that X is nonsingular. Thus, we get $G = XB = \frac{1}{3}\begin{bmatrix} -2 & 4 \end{bmatrix}$.

2. Consider the inverted pendulum with disturbances v, w and $\tilde{B} = \begin{bmatrix} 1 & 1 \end{bmatrix}^T$. Assume that $V = W = 1$. The Kalman–Bucy filter is determined via the filter ARE, yielding

$$Y_* = (1+\sqrt{2}) \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}.$$

Thus, the state estimation obtained from the Kalman filter is given by the solution of

$$\dot{\hat{\mathbf{x}}}(t) = \begin{bmatrix} -1-\sqrt{2} & 1 \\ -\sqrt{2} & 0 \end{bmatrix} \hat{\mathbf{x}}(t) + \begin{bmatrix} 0 \\ 1 \end{bmatrix} \mathbf{u}(t) + (1+\sqrt{2}) \begin{bmatrix} 1 \\ 1 \end{bmatrix} \mathbf{y}(t).$$

80.6 Control Design for LTI Systems

This section provides the background for some of the most important control design methods.

Definitions:

A **(feedback) controller** for an LTI system is given by another LTI system

$$\begin{aligned} \dot{\mathbf{r}}(t) &= E\mathbf{r}(t) + F\mathbf{y}(t), \\ \mathbf{u}(t) &= H\mathbf{r}(t) + K\mathbf{y}(t), \end{aligned}$$

where $E \in \mathbb{R}^{N \times N}$, $F \in \mathbb{R}^{N \times p}$, $H \in \mathbb{R}^{m \times N}$, $K \in \mathbb{R}^{m \times p}$, and the "output" $\mathbf{u}(t)$ of the controller serves as the input for the original LTI system.

If E, F, H are zero matrices, a controller is called **static feedback**; otherwise, it is called a **dynamic compensator**.

A static feedback control law is a **state feedback** if in the controller equations, the output function $\mathbf{y}(t)$ is replaced by the state $\mathbf{x}(t)$; otherwise, it is called **output feedback**.

The **closed-loop system** resulting from inserting the control law $\mathbf{u}(t)$ obtained from a dynamic compensator into the LTI system is illustrated by the block diagram in Figure 80.3, where $\mathbf{w}$ is as in the definition of LTI systems with stochastic disturbances in Section 80.5 and $\mathbf{z}$ will only be needed later when defining the H_∞ control problem.

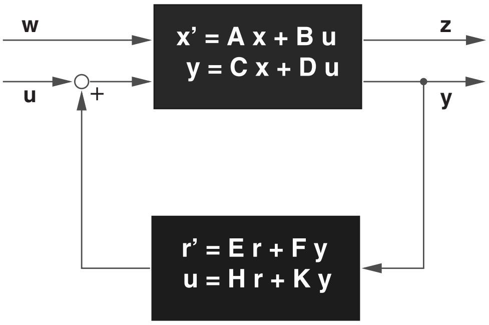

FIGURE 80.3 Closed-loop diagram of an LTI system and a dynamic compensator.

The linear-quadratic optimization (optimal control) problem

$$\min_{\mathbf{u} \in L_2(0,\infty;\mathbb{R}^m)} \mathcal{J}(\mathbf{u}), \quad \text{where } \mathcal{J}(\mathbf{u}) = \frac{1}{2} \int_0^\infty \left(\mathbf{y}(t)^T Q \mathbf{y}(t) + \mathbf{u}(t)^T R \mathbf{u}(t) \right) dt$$

subject to the dynamical constraint given by an LTI system is called the **linear-quadratic regulator (LQR) problem**.

The linear-quadratic optimization (optimal control) problem

$$\min_{\mathbf{u}\in L_2(0,\infty;\mathbb{R}^m)} \mathcal{J}(\mathbf{u}), \quad \text{where } \mathcal{J}(\mathbf{u}) = \lim_{t_f\to\infty} \frac{1}{2t_f} E\left[\int_{-t_f}^{t_f} \left(\mathbf{y}(t)^T Q\mathbf{y}(t) + \mathbf{u}(t)^T R\mathbf{u}(t)\right)\, dt\right]$$

subject to the dynamical constraint given by an LTI system with stochastic disturbances is called the **linear-quadratic Gaussian (LQG) problem**.

Consider an LTI system where inputs and outputs are split into two parts, so that instead of $B\mathbf{u}(t)$ we have

$$B_1\mathbf{w}(t) + B_2\mathbf{u}(t),$$

and instead of $\mathbf{y}(t) = C\mathbf{x}(t) + D\mathbf{u}(t)$, we write

$$\begin{aligned}\mathbf{z}(t) &= C_1\mathbf{x}(t) + D_{11}\mathbf{w}(t) + D_{12}\mathbf{u}(t),\\ \mathbf{y}(t) &= C_2\mathbf{x}(t) + D_{21}\mathbf{w}(t) + D_{22}\mathbf{u}(t),\end{aligned}$$

where $\mathbf{u}(t) \in \mathbb{R}^{m_2}$ denotes the control input, $\mathbf{w}(t) \in \mathbb{R}^{m_1}$ is an **exogenous input** that may include noise, linearization errors, and unmodeled dynamics, $\mathbf{y}(t) \in \mathbb{R}^{p_2}$ contains **measured outputs**, while $\mathbf{z}(t) \in \mathbb{R}^{p_1}$ is the **regulated output** or an **estimation error**. Let $G = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22}\end{bmatrix}$ denote the corresponding transfer function such that

$$\begin{bmatrix}\mathbf{Z}\\ \mathbf{Y}\end{bmatrix} = \begin{bmatrix} G_{11} & G_{12} \\ G_{21} & G_{22}\end{bmatrix}\begin{bmatrix}\mathbf{W}\\ \mathbf{U}\end{bmatrix},$$

where $\mathbf{Y}, \mathbf{Z}, \mathbf{U}, \mathbf{W}$ denote the Laplace transforms of $\mathbf{y}, \mathbf{z}, \mathbf{u}, \mathbf{w}$.

The **optimal H_∞ control problem** is then to determine a dynamic compensator

$$\begin{aligned}\dot{\mathbf{r}}(t) &= E\mathbf{r}(t) + F\mathbf{y}(t),\\ \mathbf{u}(t) &= H\mathbf{r}(t) + K\mathbf{y}(t),\end{aligned}$$

with $E \in \mathbb{R}^{N\times N}$, $F \in \mathbb{R}^{N\times p_2}$, $H \in \mathbb{R}^{m_2\times N}$, $K \in \mathbb{R}^{m_2\times p_2}$ and transfer function $M(s) = H(sI - E)^{-1}F + K$ such that the resulting closed-loop system

$$\begin{aligned}&\dot{\mathbf{x}}(t) = (A + B_2KZ_1C_2)\mathbf{x}(t) + (B_2Z_2H)\mathbf{r}(t) + (B_1 + B_2KZ_1D_{21})\mathbf{w}(t),\\ &\dot{\mathbf{r}}(t) = FZ_1C_2\mathbf{x}(t) + (E + FZ_1D_{22}H)\mathbf{r}(t) + FZ_1D_{21}\mathbf{w}(t),\\ &\mathbf{z}(t) = (C_1 + D_{12}Z_2KC_2)\mathbf{x}(t) + D_{12}Z_2H\mathbf{r}(t) + (D_{11} + D_{12}KZ_1D_{21})\mathbf{w}(t),\end{aligned}$$

with $Z_1 = (I - D_{22}K)^{-1}$ and $Z_2 = (I - KD_{22})^{-1}$,

- is **internally stable**, i.e., the solution of the system with $\mathbf{w}(t) \equiv 0$ is asymptotically stable, and
- the closed-loop transfer function $T_{zw}(s) = G_{22}(s) + G_{21}(s)M(s)(I - G_{11}(s)M(s))^{-1}G_{12}(s)$ from $\mathbf{w}$ to $\mathbf{z}$ is minimized in the H_∞-norm.

The **suboptimal H_∞ control problem** is to find an internally stabilizing controller so that

$$\|T_{zw}\|_{H_\infty} < \gamma,$$

where $\gamma > 0$ is a robustness threshold.

Facts:

1. If $D = 0$ and the LTI system is both stabilizable and detectable, the weighting matrix Q is positive semidefinite, and R is positive definite, then the solution of the LQR problem is given by the state feedback controller

$$\mathbf{u}_*(t) \;=\; -R^{-1}B^T X_* \mathbf{x}(t), \qquad t \geq 0,$$

   where X_* is the unique stabilizing solution of the LQR ARE,

$$0 = C^T Q C + A^T X + XA - XBR^{-1}B^T X.$$

2. The LQR problem does not require an observer equation — inserting $\mathbf{y}(t) = C\mathbf{x}(t)$ into the cost functional, we obtain a problem formulation depending only on states and inputs:

$$\begin{aligned}\mathcal{J}(\mathbf{u}) &= \frac{1}{2}\int_0^\infty \big(\mathbf{y}(t)^T Q \mathbf{y}(t) + \mathbf{u}(t)^T R \mathbf{u}(t)\big)\, dt \\ &= \frac{1}{2}\int_0^\infty \big(\mathbf{x}(t)^T C^T Q C \mathbf{x}(t) + \mathbf{u}(t)^T R \mathbf{u}(t)\big)\, dt.\end{aligned}$$

3. Under the given assumptions, it can also be shown that X_* is symmetric and the unique positive semidefinite matrix among all solutions of the LQR ARE.
4. The assumptions for the feedback solution of the LQR problem can be weakened in several aspects; see, e.g., [Gee89] and [SSC95].
5. Assuming that
   (a) $\mathbf{w}$ and $\mathbf{v}$ are uncorrelated stochastic processes,
   (b) the initial state $\mathbf{x}^0$ is a Gaussian zero-mean random variable, uncorrelated to $\mathbf{w}$ and $\mathbf{v}$,
   (c) (A, B) is controllable and (A, C) is observable,

   the solution to the LQG problem is given by the feedback controller

$$\mathbf{u}(t) = -R^{-1}B^T X_* \hat{\mathbf{x}}(t),$$

   where X_* is the solution of the LQR ARE and $\hat{\mathbf{x}}$ is the Kalman–Bucy filter

$$\dot{\hat{\mathbf{x}}}(t) = (A - BR^{-1}B^T X_* - Y_* C^T V^{-1} C)\hat{\mathbf{x}}(t) + Y_* C^T V^{-1}\mathbf{y}(t),$$

   corresponding to the closed-loop system resulting from the LQR solution with Y_* being the stabilizing solution of the corresponding filter ARE.
6. In principle, there is no restriction on the degree N of the H_∞ controller, although smaller dimensions N are preferred for practical implementation and computation.
7. The state-space solution to the H_∞ suboptimal control problem [DGK$^+$89] relates H_∞ control to AREs: under the assumptions that
   (a) (A, B_k) is stabilizable and (A, C_k) is detectable for $k = 1, 2$,
   (b) $D_{11} = 0$, $D_{22} = 0$, and

$$D_{12}^T \begin{bmatrix} C_1 & D_{12} \end{bmatrix} = \begin{bmatrix} 0 & I \end{bmatrix}, \quad \begin{bmatrix} B_1 \\ D_{21} \end{bmatrix} D_{21}^T = \begin{bmatrix} 0 \\ I \end{bmatrix},$$

a suboptimal H_∞ controller exists if and only if the AREs

$$\begin{aligned}0 &= C_1^T C_1 + AX + XA^T + X\left(\frac{1}{\gamma^2}B_1B_1^T - B_2B_2^T\right)X,\\ 0 &= B_1^T B_1 + A^TY + YA + Y\left(\frac{1}{\gamma^2}C_1C_1^T - C_2C_2^T\right)Y\end{aligned}$$

both have positive semidefinite stabilizing solutions X_∞ and Y_∞, respectively, satisfying the spectral radius condition

$$\rho(XY) < \gamma^2.$$

8. The solution of the optimal H_∞ control problem can be obtained by a bisection method (or any other root-finding method) minimizing γ based on the characterization of an H_∞ suboptimal controller given in Fact 7, starting from γ_0 for which no suboptimal H_∞ controller exists and γ_1 for which the above conditions are satisfied.
9. The assumptions made for the state-space solution of the H_∞ control problem can mostly be relaxed.
10. The robust numerical solution of the H_∞ control problem is a topic of ongoing research — the solution via AREs may suffer from several difficulties in the presence of roundoff errors and should be avoided if possible. One way out is a reformulation of the problem using structured generalized eigenvalue problems; see [BBM$^+$99], [BBM$^+$07], [CS92], and [GL97].
11. Once a (sub-)optimal γ is found, it remains to determine a realization of the H_∞ controller. One possibility is the *central (minimum entropy) controller* [ZDG96]:

$$\begin{aligned}E &= A + \frac{1}{\gamma^2}B_1B_1^T - B_2B_2^TX_\infty - Z_\infty Y_\infty C_2^T C_2,\\ F &= Z_\infty Y_\infty C_2^T, \quad K \;=\; -B_2^T X_\infty, \quad H \;=\; 0,\end{aligned}$$

where

$$Z_\infty = \left(I - \frac{1}{\gamma^2}Y_\infty X_\infty\right)^{-1}.$$

Examples:

1. The cost functional in the LQR and LQG problems values the energy needed to reach the desired state by the weighting matrix R on the inputs. Thus, usually

$$R = \operatorname{diag}(\rho_1, \ldots, \rho_m).$$

The weighting on the states or outputs in the LQR or LQG problems is usually used to penalize deviations from the desired state of the system and is often also given in diagonal form. Common examples of weighting matrices are $R = \rho I_m$, $Q = \gamma I_p$ for $\rho, \gamma > 0$.

2. The solution to the LQR problem for the inverted pendulum with $Q = R = 1$ is given via the stabilizing solution of the LQR ARE, which is

$$X_* = \begin{bmatrix} 2\sqrt{1+\sqrt{2}} & 1+\sqrt{2} \\ 1+\sqrt{2} & \sqrt{2}\sqrt{1+\sqrt{2}} \end{bmatrix},$$

resulting in the state feedback law

$$\mathbf{u}(t) = -\begin{bmatrix} 1+\sqrt{2} & \sqrt{2}\sqrt{1+\sqrt{2}} \end{bmatrix} \mathbf{x}(t).$$

The eigenvalues of the closed-loop system are (up to four digits) $\sigma(A - BR^{-1}B^T X_*) = \{-1.0987 \pm 0.4551i\}$.

3. The solution to the LQG problem for the inverted pendulum with Q, R as above and uncertainties $\mathbf{v}, \mathbf{w}$ with $\tilde{B} = \begin{bmatrix} 1 & 1 \end{bmatrix}^T$ is obtained by combining the LQR solution derived above with the Kalman–Bucy filter obtained as in the examples part of the previous section. Thus, we get the LQG control law

$$\mathbf{u}(t) = -\begin{bmatrix} 1+\sqrt{2} \ \sqrt{2}\sqrt{1+\sqrt{2}} \end{bmatrix} \hat{\mathbf{x}}(t),$$

where $\hat{\mathbf{x}}$ is the solution of

$$\dot{\hat{\mathbf{x}}}(t) = -\begin{bmatrix} 1+\sqrt{2} & -1 \\ 1+2\sqrt{2} & \sqrt{2}\sqrt{1+\sqrt{2}} \end{bmatrix} \mathbf{x}(t) + (1+\sqrt{2}) \begin{bmatrix} 1 \\ 1 \end{bmatrix} \mathbf{y}(t).$$

81.1 Introduction

Fourier analysis has been employed with great success in a wide range of applications. The underlying theory is based on a small set of linear transforms on particular linear spaces. It may, in fact, be best to refer to two parallel theories of Fourier analysis—the function/functional theory and the discrete theory—according to whether these linear spaces are infinite or finite dimensional. The function/functional theory involves infinite dimensional spaces of functions on $\mathbb{R}^n$ and can be further divided into two "subtheories"—one concerned with functions that are periodic on $\mathbb{R}^n$ (or can be treated as periodic extensions of functions on finite subregions) and one concerned with more general functions and functionals on $\mathbb{R}^n$. This theory played the major role in applications up to half a century or so ago. However, the tools from the discrete theory (involving vectors in $\mathbb{C}^N$ instead of functions on $\mathbb{R}^n$) are much more easily implemented on digital computers. This became of interest both because much of the function/functional theory analysis can be closely approximated within the discrete theory and because the discrete theory is a natural setting for functions known only by samplings. In addition, "fast" algorithms for computing the discrete transforms were developed, allowing discrete analysis to be done very quickly even with very large data sets. For these reasons the discrete theory has become extremely important in modern applications, and its utility, in turn, has greatly extended the applicability of Fourier analysis.

In the first part of this chapter, elements of the function/functional theory are presented and illustrated. For expediency, attention will be restricted to functions and functionals over subsets of $\mathbb{R}^1$. A corresponding review of the analogous elements of the discrete theory then follows, with a discussion of the relations between the two theories following that. Finally, one of the fast algorithms is described and the extent to which this algorithm improves speed and applicability is briefly discussed.

The development here is necessarily abbreviated and covers only a small fraction of the theory and applications of Fourier analysis. The reader interested in more complete treatments of the subject is encouraged to consult the references given throughout this chapter.

81.2 The Function/Functional Theory

Definitions:

The following function spaces often arise in Fourier analysis. In each case $\mathcal{I}$ is a subinterval of $\mathbb{R}$, and all functions on $\mathcal{I}$ are assumed to be complex valued.

- $\mathcal{C}^0(\mathcal{I})$, the normed linear space of bounded and continuous functions on $\mathcal{I}$ with the norm $\|f\| = \sup\{|f(x)| : x \in \mathcal{I}\}$.
- $\mathcal{L}^1(\mathcal{I})$, the normed linear space of absolutely integrable functions on $\mathcal{I}$ with the norm $\|f\| = \int_{\mathcal{I}} |f(x)|\, dx$.
- $\mathcal{L}^2(\mathcal{I})$, the inner product space of square integrable functions on $\mathcal{I}$ with the inner product $\langle f, g\rangle = \int_{\mathcal{I}} f(x)\overline{g(x)}\, dx$.

If $\mathcal{I}$ is not specified, then $\mathcal{I} = \mathbb{R}$.

Let $\phi \in \mathcal{L}^1(\mathbb{R})$. The **Fourier transform** $\mathcal{F}[\phi]$ and the **inverse Fourier transform** $\mathcal{F}^{-1}[\phi]$ of ϕ are the functions

$$\mathcal{F}[\phi]|_x = \int_{-\infty}^{\infty} \phi(y)e^{-i2\pi xy}dy \qquad \text{and} \qquad \mathcal{F}^{-1}[\phi]|_x = \int_{-\infty}^{\infty} \phi(y)e^{i2\pi xy}dy\,.$$

Additionally, the terms "Fourier transform" and "inverse Fourier transform" can refer to the processes for computing these functions from ϕ.

A function ϕ on $\mathbb{R}$ is said to be **periodic** if there is a positive value p, called a **period** for ϕ, such that

$$\phi(x+p) = \phi(x) \quad \forall x \in \mathbb{R}\,.$$

The smallest period, if it exists, is called the **fundamental period**.

The **Fourier series** for a suitably integrable, periodic function ϕ with period $p > 0$ is the infinite series

$$\sum_{k=-\infty}^{\infty} c_k\, e^{i2\pi\omega_k x}$$

where

$$\omega_k = \frac{k}{p} \qquad \text{and} \qquad c_k = \frac{1}{p}\int_0^p \phi(y)e^{-i2\pi\omega_k y}dy.$$

The theory for Fourier transforms and series can be generalized so that the requirement of ϕ being "suitably integrable" can be greatly relaxed (see [How01, Chap. 20, 30–34] or [Str94, Chap. 1–4]). Within this generalized theory the **delta function** at $a \in \mathbb{R}$, δ_a, is the functional limit

$$\delta_a(x) = \lim_{\epsilon\to 0^+} \frac{1}{2\epsilon}\text{pulse}_\epsilon(x-a) \qquad \text{where} \qquad \text{pulse}_\epsilon(s) = \begin{cases} 1 & \text{if } |s| \le \epsilon \\ 0 & \text{if } |s| > \epsilon \end{cases}.$$

That is, δ_a is the (generalized) function such that

$$\int_{-\infty}^{\infty} \psi(x)\delta_a(x)\, dx = \lim_{\epsilon\to 0^+} \int_{-\infty}^{\infty} \psi(x)\frac{1}{2\epsilon}\text{pulse}_\epsilon(x-a)\, dx$$

whenever ψ is a function continuous at a.

An **array of delta functions** is any expression of the form

$$\sum_{k=-\infty}^{\infty} c_k\delta_{k\Delta x}$$

where $\Delta x > 0$ is fixed (the **spacing** of the array) and $c_k \in \mathbb{C}$ for each $k \in \mathbb{Z}$. If the array is also periodic with period p, then the corresponding **index period** is the positive integer N such that

$$p = N\Delta x \qquad \text{and} \qquad \phi_{k+N} = \phi_k \quad \forall\, k \in \mathbb{Z}.$$

The **convolution** $\phi * \psi$ of a suitably integrable pair of functions ϕ and ψ on $\mathbb{R}$ is the function given by

$$\phi * \psi(x) = \int_{-\infty}^{\infty} \phi(x-y)\psi(y)\, dy\,.$$

Facts:

All the following facts except those with specific reference can be found in [How01] or [Str94].

1. Warning: Slight variations of the above integral formulas, e.g.,

$$\frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \phi(y) e^{-ixy} dy \qquad \text{and} \qquad \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} \phi(y) e^{ixy} dy,$$

   are also often used to define, respectively, $\mathcal{F}[\phi]$ and $\mathcal{F}^{-1}[\phi]$ (or even $\mathcal{F}^{-1}[\phi]$ and $\mathcal{F}[\phi]$). There is little difference in the resulting "Fourier theories," but the formulas resulting from using different versions of the Fourier transforms do differ in details. Thus, when computing Fourier transforms using different tables or software, it is important to take into account the specific integral formulas on which the table or software is based.
2. Both $\mathcal{F}$ and $\mathcal{F}^{-1}$ are continuous, linear mappings from $\mathcal{L}^1(\mathbb{R})$ into $\mathcal{C}^0(\mathbb{R})$. Moreover, if both ϕ and $\mathcal{F}[\phi]$ are absolutely integrable, then $\mathcal{F}^{-1}[\mathcal{F}[\phi]] = \phi$.
3. In the generalized theory (which will be assumed hereafter), $\mathcal{F}$ and $\mathcal{F}^{-1}$ are defined on a linear space of (generalized) functions that contains all elements of $\mathcal{L}^1(\mathbb{R})$ and $\mathcal{L}^2(\mathbb{R})$, all Fourier transforms of elements of $\mathcal{L}^1(\mathbb{R})$ and $\mathcal{L}^2(\mathbb{R})$, all piecewise continuous periodic functions, the delta functions, and all periodic arrays of delta functions. $\mathcal{F}$ and $\mathcal{F}^{-1}$ are one-to-one linear mappings from this space onto this space, and are inverses of each other.
4. Every nonconstant, piecewise continuous periodic function has a fundamental period, and every period of such a function is an integral multiple of that fundamental period. Moreover, any two Fourier series for a single periodic function computed using two different periods will be identical after simplification (e.g., after eliminating zero-valued terms).
5. The Fourier series $\sum_{k\in\mathbb{Z}} c_k e^{i2\pi\omega_k x}$ for a periodic function ϕ with period p can be written in *trigonometric form*

$$c_0 + \sum_{k=1}^{\infty} \left[a_k \cos(2\pi\omega_k x) + b_k \sin(2\pi\omega_k x)\right]$$

   where

$$a_k = c_k + c_{-k} = \frac{2}{p} \int_0^p \phi(x) \cos(2\pi\omega_k x)\, dx$$

   and

$$b_k = ic_k - ic_{-k} = \frac{2}{p} \int_0^p \phi(x) \sin(2\pi\omega_k x)\, dx\,.$$

6. On $\mathcal{I} = (0, p)$ (or any other interval $\mathcal{I}$ of length p), the exponentials

$$\left\{ e^{i2\pi\omega_k x} : \omega_k = k/p,\ k \in \mathbb{Z} \right\}$$

form an orthogonal set in $\mathcal{L}^2(\mathcal{I})$, and the Fourier series $\sum_{k\in\mathbb{Z}} c_k\, e^{i2\pi\omega_k x}$ for a periodic function ϕ with period p is simply the expansion of ϕ with respect to this orthogonal set. That is,

$$c_k = \frac{\langle \phi(x), e^{i2\pi\omega_k x}\rangle}{\|e^{i2\pi\omega_k x}\|^2} \qquad \forall\, k \in \mathbb{Z}.$$

Similar comments apply regarding the trigonometric form for the Fourier series and the set

$$\{1,\, \cos(2\pi\omega_k x),\, \sin(2\pi\omega_k x)\, :\, \omega_k = k/p,\, k \in \mathbb{N}\}\,.$$

7. A periodic function ϕ can be identified with its Fourier series $\sum_{k\in\mathbb{Z}} c_k e^{i2\pi\omega_k x}$ under a wide range of criteria. In particular:
   (a) If ϕ is smooth, then its Fourier series converges uniformly to ϕ.
   (b) If ϕ is piecewise smooth, then its Fourier series converges pointwise to ϕ everywhere ϕ is continuous.
   (c) If ϕ is square-integrable on $(0,p)$, then
   $$\lim_{(M,N)\to(-\infty,\infty)} \int_0^p \left|\phi(x) - \sum_{k=M}^{N} c_k\, e^{i2\pi\omega_k x}\right|^2 dx = 0.$$
   (d) Within the generalized theory,
   $$\lim_{(M,N)\to(-\infty,\infty)} \int_{-\infty}^{\infty} \psi(x) \left[\phi(x) - \sum_{k=M}^{N} c_k\, e^{i2\pi\omega_k x}\right] dx = 0$$
   whenever ψ is a sufficiently smooth function vanishing sufficiently rapidly at infinity (e.g., any Gaussian function).
8. [BH95, p. 186] Suppose ϕ is a periodic function with Fourier series $\sum_{k\in\mathbb{Z}} c_k e^{i2\pi\omega_k x}$. If ϕ is m-times differentiable on $\mathbb{R}$ and $\phi^{(m)}$ is piecewise continuous for some $m \in \mathbb{N}$, then there is a finite constant β such that
   $$|c_k| \le \frac{\beta}{|k|^m} \qquad \forall\, k \in \mathbb{Z}.$$
9. For each $a \in \mathbb{R}$ and function ϕ continuous at a:
   $$\int_{-\infty}^{\infty} \phi(x)\delta_a(x)\, dx = \phi(a) \qquad \text{and} \qquad \phi\delta_a = \phi(a)\delta_a.$$
10. For each $a \in \mathbb{R}$:
    (a) $\mathcal{F}[\delta_a]|_x = e^{-i2\pi ax}$ and $\mathcal{F}^{-1}[e^{-i2\pi ax}] = \delta_a$.
    (b) $\mathcal{F}[e^{i2\pi ax}]|_x = \delta_a$ and $\mathcal{F}^{-1}[\delta_a]|_x = e^{i2\pi ax}$.
11. A function ϕ is periodic with period p and Fourier series $\sum_{k\in\mathbb{Z}} c_k e^{i2\pi\omega_k x}$ if and only if its transforms are the arrays
    $$\mathcal{F}[\phi] = \sum_{k=-\infty}^{\infty} c_k \delta_{k\Delta\omega} \qquad \text{and} \qquad \mathcal{F}^{-1}[\phi] = \sum_{k=-\infty}^{\infty} c_{-k} \delta_{k\Delta\omega}$$
    with spacing $\Delta\omega = 1/p$.
12. If
    $$\phi = \sum_{k=-\infty}^{\infty} \phi_k \delta_{k\Delta x}$$
    is a periodic array with spacing Δx, period p, and corresponding index period N, then:

(a) The Fourier series for ϕ is given by

$$\sum_{n=-\infty}^{\infty} \Phi_n \, e^{i2\pi\omega_n x}$$

where $\omega_n = n/p = n/(N\Delta x)$ and

$$\Phi_n = \frac{1}{N\Delta x} \sum_{k=0}^{N-1} \phi_k \, e^{-i2\pi kn/N} .$$

(b) The Fourier transforms of ϕ are also periodic arrays of delta functions with index period N. Both have spacing $\Delta\omega = 1/p$ and period $P = 1/\Delta x$. These transforms are given by

$$\mathcal{F}[\phi] = \sum_{n=-\infty}^{\infty} \Phi_n \delta_{n\Delta\omega} \qquad \text{and} \qquad \mathcal{F}^{-1}[\phi] = \sum_{n=-\infty}^{\infty} \Phi_{-n} \delta_{n\Delta\omega} .$$

13. (*Translation identities*) Let f, F, g, and G be functions with $F = \mathcal{F}[f]$ and $G = \mathcal{F}[g]$, and let $\alpha \in \mathbb{R}$. Then

$$g(x) = f(x - \alpha) \quad \forall x \in \mathbb{R} \qquad \Leftrightarrow \qquad G(y) = e^{-i2\pi\alpha y} F(y) \quad \forall y \in \mathbb{R} .$$

Similarly,

$$g(x) = e^{i2\pi\alpha x} f(x) \quad \forall x \in \mathbb{R} \qquad \Leftrightarrow \qquad G(y) = F(y - \alpha) \quad \forall y \in \mathbb{R} .$$

14. (*Convolution identities*) Let f, F, g, and G be functions with $F = \mathcal{F}[f]$ and $G = \mathcal{F}[g]$. Then, provided the convolutions exist,

$$\mathcal{F}[fg] = F * G \qquad \text{and} \qquad \mathcal{F}[f * g] = FG .$$

Examples:

1. For $\alpha > 0$,

$$\begin{aligned} \mathcal{F}[\text{pulse}_\alpha]|_x &= \int_{-\infty}^{\infty} \text{pulse}_\alpha(y) e^{-i2\pi xy} dy \\ &= \int_{-\alpha}^{\alpha} e^{-i2\pi xy} dy \\ &= \frac{e^{i2\pi\alpha x} - e^{-i2\pi\alpha x}}{i2\pi x} = \frac{\sin(2\pi\alpha x)}{\pi x} . \end{aligned}$$

2. Let f be the periodic function,

$$f(x) = \begin{cases} |x| & \text{for } -1 \le x < 1 \\ f(x-2) & \text{for all } x \in \mathbb{R} \end{cases} .$$

The period of this function is $p = 2$, and its Fourier series $\sum_{k \in \mathbb{Z}} c_k e^{i2\pi\omega_k x}$ is given by

$$\omega_k = \frac{k}{2} \qquad (\text{so } e^{i2\pi\omega_k x} = e^{i\pi kx})$$

and

$$c_k = \frac{1}{2}\int_0^2 \left\{\begin{array}{cl} |x| & \text{if } x < 1 \\ |x-2| & \text{if } 1 < x \end{array}\right\} e^{-i\pi kx}\,dx$$
$$= \begin{cases} 1/2 & \text{if } k = 0 \\ (k\pi)^{-2}\left[(-1)^k - 1\right] & \text{if } k \neq 0 \end{cases}.$$

Since f is continuous and piecewise smooth, f equals its Fourier series,

$$f(x) = \frac{1}{2} + \sum_{k\in\mathbb{Z}\setminus\{0\}} \frac{(-1)^k - 1}{k^2\pi^2} e^{i\pi kx} \qquad \forall\, x \in \mathbb{R}\,.$$

Moreover,

$$\mathcal{F}[f] = \frac{1}{2}\delta_0 + \sum_{k\in\mathbb{Z}\setminus\{0\}} \frac{(-1)^k - 1}{k^2\pi^2} \delta_{k/2}\,.$$

3. Let

$$\phi = \sum_{k=-\infty}^{\infty} \phi_k \delta_{\Delta x}$$

be the periodic array with spacing $\Delta x = 1/3$, index period $N = 4$, and coefficients

$$\phi_0 = 0, \quad \phi_1 = 1, \quad \phi_2 = 2, \quad \text{and} \quad \phi_3 = 1\,.$$

The period p of ϕ is then

$$p = N\Delta x = 4 \cdot \frac{1}{3} = \frac{4}{3}\,.$$

Its Fourier transform $\Phi = \mathcal{F}[\phi]$ is also a periodic array,

$$\Phi = \sum_{n=-\infty}^{\infty} \Phi_n \delta_{n\Delta\omega}\,,$$

with index period $N = 4$. The spacing $\Delta\omega$ and period P of Φ are determined, respectively, from the period p and spacing Δx of ϕ by

$$\Delta\omega = \frac{1}{p} = \frac{1}{4/3} = \frac{3}{4} \qquad \text{and} \qquad P = \frac{1}{\Delta x} = \frac{1}{1/3} = 3.$$

The coefficients are given by

$$\begin{aligned} \Phi_n &= \frac{1}{N\Delta x} \sum_{k=0}^{N-1} \phi_k\, e^{-i2\pi kn/N} \\ &= \frac{1}{N\Delta x}\left[\phi_0 e^{-i2\pi 0n/4} + \phi_1 e^{-i2\pi 1n/4} + \phi_2 e^{-i2\pi 2n/4} + \phi_3 e^{-i2\pi 3n/4}\right] \\ &= \frac{1}{4(1/3)}\left[0e^0 + 1e^{-in\pi/2} + 2e^{-in\pi} + 1e^{-i3n\pi/2}\right] \\ &= \frac{3}{4}\left[0 + (-i)^n + 2 + i^n\right]. \end{aligned}$$

Thus,

$$\Phi_0 = 3, \quad \Phi_1 = \frac{3}{2}, \quad \Phi_2 = 0 \quad \text{and} \quad \Phi_3 = \frac{3}{2}\,.$$

Applications:

1. [BC01, p. 155] or [Col88, pp. 159–160] (*Partial differential equations*) Using polar coordinates, the steady-state temperature u at position (r,θ) on a uniform, insulated disk of radius 1 satisfies
$$r^2\frac{\partial^2 u}{\partial r^2}+r\frac{\partial u}{\partial r}+\frac{\partial^2 u}{\partial \theta^2}=0 \qquad \text{for } 0<r<1\,.$$
As a function of θ, u is periodic with period 2π and has (equivalent) Fourier series
$$\sum_{k=-\infty}^{\infty} c_k e^{ikx} \qquad \text{and} \qquad c_0+\sum_{k=1}^{\infty}\left[a_k\cos(kx)+b_k\sin(kx)\right]$$
where the coefficients are functions of r. If u satisfies the boundary condition
$$u(1,\theta)=f(\theta) \qquad \text{for } 0\le\theta<2\pi$$
for some function f on $[0,2\pi)$, then the coefficients in the series can be determined, yielding
$$u(r,\theta)=\sum_{k=-\infty}^{\infty} r^k\gamma_k e^{ik\theta}=\gamma_0+\sum_{k=1}^{\infty}\left[r^k\alpha_k\cos(k\theta)+r^k\beta_k\sin(k\theta)\right]$$
where
$$\gamma_k=\frac{1}{2\pi}\int_0^{2\pi} f(\theta)e^{-ik\theta}\,d\theta\,,$$
$$\alpha_k=\frac{1}{\pi}\int_0^{2\pi} f(\theta)\cos(k\theta)\,d\theta, \qquad \text{and} \qquad \beta_k=\frac{1}{\pi}\int_0^{2\pi} f(\theta)\sin(k\theta)\,d\theta\,.$$

2. (*Systems analysis*) In systems analysis, a "system" S transforms any "input" function f_I to a corresponding "output" function $f_O=S[f_I]$. Often, the output of S can be described by the convolution formula
$$f_O=h*f_I$$
where h is some fixed function called the impulse response of the system. The corresponding Fourier transform $H=\mathcal{F}[h]$ is the system's transfer function. By the convolution identity, the output is also given by
$$f_O=\mathcal{F}^{-1}[HF_I] \qquad \text{where } F_I=\mathcal{F}[f_I]\,.$$
Two such systems are
   - A delayed output system, for which
$$h(x)=\delta_T(x) \qquad \text{and} \qquad H(\omega)=e^{-i2\pi T\omega}$$
for some $T>0$. Then
$$f_O(x)=f_I*\delta_T(x)=\int_{-\infty}^{\infty} f_I(x-y)\delta_T(y)dy=f_I(x-T)\,.$$
   - [ZTF98, p. 178] or [How01, p. 477] An ideal low pass filter, for which
$$h(x)=\frac{\sin(2\pi\Omega x)}{\pi x} \qquad \text{and} \qquad H(y)=\mathrm{pulse}_\Omega(y)$$
for some $\Omega>0$. If an input function f_I is periodic with Fourier series $\sum_{k\in\mathbb{Z}} c_k e^{i2\pi\omega_k x}$ (and Ω is not a period for f_I), then

$$\begin{aligned} HF_I &= \text{pulse}_\Omega \cdot \sum_{k=-\infty}^{\infty} c_k \delta_{\omega_k} \\ &= \sum_{k-\infty}^{\infty} c_k \, \text{pulse}_\Omega(\omega_k) \delta_{\omega_k} \\ &= \sum_{k-\infty}^{\infty} c_k \begin{Bmatrix} 1 & \text{if } |\omega_k| < \Omega \\ 0 & \text{if } |\omega_k| > \Omega \end{Bmatrix} \delta_{\omega_k} = \sum_{|\omega_k|<\Omega} c_k \delta_{\omega_k} \,. \end{aligned}$$

Thus,

$$f_O(x) = \mathcal{F}^{-1}[HF_I]|_x = \mathcal{F}^{-1}\left[\sum_{|\omega_k|<\Omega} c_k \delta_{\omega_k} \right]\Bigg|_x = \sum_{|\omega_k|<\Omega} c_k \, e^{i2\pi\omega_k x} \,.$$

3. [ZTF98, pp. 520–521] (*Deconvolution*) Suppose S is a system given by

$$S[f_I] = h * f_I \,,$$

but with h and $H = \mathcal{F}[h]$ being unknown. Since

$$f_O = \mathcal{F}^{-1}[HF_I] \qquad \text{where } F_I = \mathcal{F}[f_I] \,,$$

both h and H can be determined as follows:

- Find the output $f_O = S[f_I]$ for some known input f_I for which $F_I = \mathcal{F}[f_I]$ is never zero.
- Compute

$$H = \frac{F_O}{F_I} \qquad \text{where } F_O = \mathcal{F}[f_O] \,.$$

- Compute $h = \mathcal{F}^{-1}[H]$.

Similarly, an input f_I can be reconstructed from an output f_O by

$$f_I = \mathcal{F}^{-1}\left[\frac{F_O}{H}\right]$$

provided the transfer function H is known and is never zero.

81.3 The Discrete Theory

Definitions:

In all the following, $N \in \mathbb{N}$, and the indexing of any "N items" (including rows and columns of matrices) will run from 0 to $N-1$.

An ***N*th order sequence** is an ordered list of N complex numbers,

$$(c_0, c_1, c_2, \ldots, c_{N-1}).$$

Such a sequence will often be written as the column vector

$$\mathbf{c} = [c_0, c_1, c_2, \ldots, c_{N-1}]^T \,,$$

and the kth component of the sequence will be denoted by either c_k or $[\mathbf{c}]_k$. In addition, any such sequence will be viewed as part of an infinite repeating sequence

$$(\ldots, c_{-1}, c_0, c_1, c_2, \ldots, c_{N-1}, c_N, \ldots)$$

in which $c_{N+k} = c_k$ for all $k \in \mathbb{Z}$.

Let $\mathbf{c}$ be an Nth order sequence. The (Nth order) **discrete Fourier transform** (**DFT**) $\widehat{\mathfrak{F}}_N\mathbf{c}$ and the (Nth order) **inverse discrete Fourier transform** (**inverse DFT**) $\widehat{\mathfrak{F}}_N^{-1}\mathbf{c}$ of $\mathbf{c}$ are the two Nth order sequences given by

$$[\widehat{\mathfrak{F}}_N\mathbf{c}]_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} c_k\, e^{-i2\pi kn/N} \qquad \text{and} \qquad [\widehat{\mathfrak{F}}_N^{-1}\mathbf{c}]_k = \frac{1}{\sqrt{N}} \sum_{n=0}^{N-1} c_n\, e^{i2\pi nk/N}.$$

Additionally, the terms "discrete Fourier transform" and "inverse discrete Fourier transform" can refer to the processes for computing these sequences from $\mathbf{c}$.

Given two Nth order sequences $\mathbf{a}$ and $\mathbf{b}$, the corresponding product $\mathbf{ab}$ and convolution $\mathbf{a} * \mathbf{b}$ are the Nth order sequences given by

$$[\mathbf{ab}]_k = a_k b_k \qquad \text{and} \qquad [\mathbf{a} * \mathbf{b}]_k = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} a_{k-j} b_j\,.$$

Facts:

All the following facts can be found in [BH95, Chaps. 2, 3] or [How01, Chaps. 38, 39].

1. Warning: Slight variations of the above summation formulas, e.g.,

$$\sum_{k=0}^{N-1} c_k\, e^{-i2\pi kn/N} \qquad \text{and} \qquad \frac{1}{N} \sum_{n=0}^{N-1} c_n\, e^{i2\pi nk/N},$$

   are also often used to define, respectively, $\widehat{\mathfrak{F}}_N\mathbf{c}$ and $\widehat{\mathfrak{F}}_N^{-1}\mathbf{c}$ (or even $\widehat{\mathfrak{F}}_N^{-1}\mathbf{c}$ and $\widehat{\mathfrak{F}}_N\mathbf{c}$).
2. $\widehat{\mathfrak{F}}_N$ and $\widehat{\mathfrak{F}}_N^{-1}$ are one-to-one linear transformations from $\mathbb{C}^N$ onto $\mathbb{C}^N$. They preserve the standard inner product and are inverses of each other.
3. Letting $w = e^{-i2\pi/N}$, the matrices (with respect to the standard basis for $\mathbb{C}^N$) for the Nth order discrete Fourier transforms (also denoted by $\widehat{\mathfrak{F}}_N$ and $\widehat{\mathfrak{F}}_N^{-1}$) are

$$\widehat{\mathfrak{F}}_N = \frac{1}{\sqrt{N}} \begin{bmatrix} 1 & 1 & 1 & 1 & \cdots & 1 \\ 1 & w^{1\cdot 1} & w^{1\cdot 2} & w^{1\cdot 3} & \cdots & w^{1(N-1)} \\ 1 & w^{2\cdot 1} & w^{2\cdot 2} & w^{2\cdot 3} & \cdots & w^{2(N-1)} \\ 1 & w^{3\cdot 1} & w^{3\cdot 2} & w^{3\cdot 3} & \cdots & w^{3(N-1)} \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & w^{(N-1)1} & w^{(N-1)2} & w^{(N-1)3} & \cdots & w^{(N-1)(N-1)} \end{bmatrix}$$

   and

$$\widehat{\mathfrak{F}}_N^{-1} = \frac{1}{\sqrt{N}} \begin{bmatrix} 1 & 1 & 1 & 1 & \cdots & 1 \\ 1 & w^{-1\cdot 1} & w^{-1\cdot 2} & w^{-1\cdot 3} & \cdots & w^{-1(N-1)} \\ 1 & w^{-2\cdot 1} & w^{-2\cdot 2} & w^{-2\cdot 3} & \cdots & w^{-2(N-1)} \\ 1 & w^{-3\cdot 1} & w^{-3\cdot 2} & w^{-3\cdot 3} & \cdots & w^{-3(N-1)} \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & w^{-(N-1)1} & w^{-(N-1)2} & w^{-(N-1)3} & \cdots & w^{-(N-1)(N-1)} \end{bmatrix}.$$

4. $\widehat{\mathfrak{F}}_N$ and $\widehat{\mathfrak{F}}_N^{-1}$ are symmetric matrices, and are complex conjugates of each other (i.e., $\left[\widehat{\mathfrak{F}}_N\right]^* = \widehat{\mathfrak{F}}_N^{-1}$).
5. (*Translation identities*) Let $\mathbf{v}$, $\mathbf{V}$, $\mathbf{w}$, and $\mathbf{W}$ be Nth order sequences with $\mathbf{V} = \widehat{\mathfrak{F}}_N \mathbf{v}$ and $\mathbf{W} = \widehat{\mathfrak{F}}_N \mathbf{w}$, and let $\alpha \in \mathbb{Z}$. Then

$$w_k = v_{k-\alpha} \quad \forall k \in \mathbb{Z} \qquad \Leftrightarrow \qquad W_n = e^{-i2\pi n\alpha/N} V_n \quad \forall n \in \mathbb{Z}\,.$$

Similarly,

$$w_k = e^{i2\pi k\alpha/N} v_k \quad \forall k \in \mathbb{Z} \qquad \Leftrightarrow \qquad W_n = V_{n-\alpha} \quad \forall n \in \mathbb{Z}\,.$$

6. (*Convolution identities*) Let $\mathbf{v}$, $\mathbf{V}$, $\mathbf{w}$, and $\mathbf{W}$ be Nth order sequences with $\mathbf{V} = \widehat{\mathfrak{F}}_N \mathbf{v}$ and $\mathbf{W} = \widehat{\mathfrak{F}}_N \mathbf{w}$. Then

$$\widehat{\mathfrak{F}}_N[\mathbf{v}\mathbf{w}] = \mathbf{V} * \mathbf{W} \qquad \text{and} \qquad \widehat{\mathfrak{F}}_N[\mathbf{v} * \mathbf{w}] = \mathbf{V}\mathbf{W}.$$

Examples:

1. The matrices for the four lowest order DFTs are $\widehat{\mathfrak{F}}_1 = [1]$,

$$\widehat{\mathfrak{F}}_2 = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}, \quad \widehat{\mathfrak{F}}_3 = \frac{1}{2\sqrt{3}} \begin{bmatrix} 2 & 2 & 2 \\ 2 & -1 - i\sqrt{3} & -1 + i\sqrt{3} \\ 2 & -1 + i\sqrt{3} & -1 - i\sqrt{3} \end{bmatrix},$$

and

$$\widehat{\mathfrak{F}}_4 = \frac{1}{2} \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & -i & -1 & i \\ 1 & -1 & 1 & -1 \\ 1 & i & -1 & -i \end{bmatrix}.$$

2. The DFT of $\mathbf{v} = [1,\, 2,\, 3,\, 4]^T$ is $\mathbf{V} = [V_0,\, V_1,\, V_2,\, V_3]^T$ where

$$\begin{bmatrix} V_0 \\ V_1 \\ V_2 \\ V_3 \end{bmatrix} = \frac{1}{2} \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & -i & -1 & i \\ 1 & -1 & 1 & -1 \\ 1 & i & -1 & -i \end{bmatrix} \begin{bmatrix} 1 \\ 2 \\ 3 \\ 4 \end{bmatrix} = \begin{bmatrix} 5 \\ -1 + i \\ -1 \\ -1 - i \end{bmatrix}.$$

Applications:

1. [CG00, p. 153] Assume

$$f(z) = \sum_{n=0}^{2M} f_n z^n$$

is the product of two known Mth order polynomials

$$g(z) = \sum_{k=0}^{M} g_k z^k \qquad \text{and} \qquad h(z) = \sum_{k=0}^{M} h_k z^k\,.$$

The coefficients of f form a sequence $\mathbf{f} = [f_0,\, f_1,\, f_2,\, \ldots,\, f_{2M}]^T$ of order $N = 2M+1$. These coefficients can be computed from the coefficients of g and h using either of the following approaches:

- Let $\mathbf{g} = [g_0, g_1, g_2, \ldots, g_{2M}]^T$ and $\mathbf{h} = [h_0, h_1, h_2, \ldots, h_{2M}]^T$ be the Nth order sequences in which g_k and h_k are the corresponding coefficients of the polynomials g and h when $k \leq M$ and are zero when $M < k \leq N$. The coefficients of f can then be computed by

$$f_k = \sum_{j=0}^{2M} g_{k-j} h_j = \sqrt{N}[\mathbf{g} * \mathbf{h}]_k \qquad \text{for } k = 0,\, 1,\, 2,\, \ldots,\, 2M\,.$$

- Let $\mathbf{F} = [F_0, F_1, F_2, \ldots, F_{2M}]^T$ be the Nth order DFT of $\mathbf{f}$, and note that, for $n = 0, 1, 2, \ldots, N-1$,

$$F_n = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} f_k\, e^{-i2\pi kn/N} = \frac{1}{\sqrt{N}} f(w^n) = \frac{1}{\sqrt{N}} h(w^n) g(w^n)$$

where $w = e^{-i2\pi/N}$. Thus, the coefficients of f can be computed by first using the formulas for g and h to compute

$$F_n = \frac{1}{\sqrt{N}} h(w^n) g(w^n) \qquad \text{for } n = 0,\, 1,\, 2,\, \ldots,\, N-1\,,$$

and then taking the inverse DFT of $\mathbf{F} = [F_0, F_1, F_2, \ldots, F_{N-1}]^T$.

2. [BH95, p. 247] Consider finding the solution $\mathbf{v} = [v_0, v_1, v_2, \ldots, v_{N-1}]^T$ to the difference equation

$$\alpha v_{k-1} + \beta v_k + \alpha v_{k+1} = f_k \qquad \text{for } k = 0,\, 1,\, 2,\, \ldots,\, N-1$$

where α and β are constants and $\mathbf{f} = [f_0, f_1, f_2, \ldots, f_{N-1}]^T$ is a known Nth order sequence. If the boundary conditions are periodic (i.e., $v_0 = v_N$ and $v_{-1} = v_{N-1}$), then setting

$$\mathbf{v} = \widehat{\mathcal{F}}_N^{-1}\mathbf{V} \qquad \text{and} \qquad \mathbf{f} = \widehat{\mathcal{F}}_N^{-1}\mathbf{F}$$

and applying the translation identities yields the sequence $\mathbf{v}$ that satisfies the periodic boundary conditions, and whose DFT, $\mathbf{V}$, satisfies

$$\sum_{n=0}^{N-1} C_n\, e^{i2\pi nk/N} = 0 \qquad \text{for } k = 0,\, 1,\, 2,\, \ldots,\, N-1$$

where

$$C_n = \left[2\alpha \cos\left(\frac{2\pi n}{N}\right) + \beta\right] V_n - F_n\,.$$

From this, it follows that the solution $\mathbf{v}$ to the original difference equation is the inverse DFT of the sequence $[V_0, V_1, V_2, \ldots, V_{N-1}]^T$ given by

$$V_n = \frac{F_n}{2\alpha \cos\left(\frac{2\pi n}{N}\right) + \beta}\,,$$

provided the denominator never vanishes.

3. A difference equation of the form just considered with periodic boundary conditions arises when considering the steady-state temperature distribution on a uniform ring containing heat sources and sinks. In this case, the temperature v, as a function of angular position θ, is modeled by the one-dimensional Poisson's equation

$$\frac{d^2 v}{d\theta^2} = f(\theta)\,,$$

where $f(\theta)$ describes the heat source/sink density at angular position θ. The discrete analog of this equation is

$$v_{k-1} - 2v_k + v_{k+1} = f_k \qquad \text{for } k = 0,\, 1,\, 2,\, \ldots,\, N-1$$

where

$$\mathbf{v} = [v_0,\, v_1,\, v_2,\, \ldots,\, v_{N-1}]^T \qquad \text{and} \qquad \mathbf{f} = [f_0,\, f_1,\, f_2,\, \ldots,\, f_{N-1}]^T$$

describe, respectively, the temperatures at N evenly spaced positions around the ring, and the net sources and sinks of thermal energy about these positions. Setting

$$\mathbf{v} = \widehat{\mathfrak{F}}_N^{-1}\mathbf{V} \qquad \text{and} \qquad \mathbf{f} = \widehat{\mathfrak{F}}_N^{-1}\mathbf{F}$$

and applying the formulas given above yields

$$\left[2\cos\left(\frac{2\pi n}{N}\right) - 2\right] V_n = F_n \qquad \text{for } n = 0,\, 1,\, 2,\, \ldots,\, N-1.$$

The coefficient on the left is nonzero when $n \neq 0$. Thus,

$$V_n = \frac{F_n}{2\cos\left(\frac{2\pi n}{N}\right) - 2} \qquad \text{for } n = 1,\, 2,\, \ldots,\, N-1.$$

However, for $n = 0$,

$$0 \cdot V_0 = F_0 = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} f_k\, e^{-i2\pi k\cdot 0/N} = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} f_k\,,$$

pointing out that, for an equilibrium temperature distribution to exist, the net applied heat energy, $\sum_{k=0}^{N-1} f_k$, must be zero. Assuming this, the last equation then implies that V_0 is arbitrary, which, since

$$V_0 = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} v_k\, e^{-i2\pi k\cdot 0/N} = \frac{1}{\sqrt{N}} \sum_{k=0}^{N-1} v_k$$

means that the given conditions are not sufficient to determine the average temperature throughout the ring.

81.4 Relating the Functional and Discrete Theories

Definitions:

Let f be a (continuous) function on a finite interval $[0, L]$. For any $N \in \mathbb{N}$ and $\Delta x > 0$ satisfying $N\Delta x \leq L$, the corresponding (**Nth order**) **sampling** (with **spacing** Δx) is the sequence

$$\mathbf{f} = [f_0,\, f_1,\, f_2,\, \ldots,\, f_{N-1}]^T \qquad \text{where } f_k = f(k\Delta x)\,.$$

Corresponding to this is the **scaled sampling**

$$\widehat{\mathbf{f}} = [\widehat{f}_0,\, \widehat{f}_1,\, \widehat{f}_2,\, \ldots,\, \widehat{f}_{N-1}]^T$$

and the **discrete approximation**

$$\widehat{f} = \sum_{k=-\infty}^{\infty} \widehat{f}_k \delta_{k\Delta x}$$

where, in both,

$$\widehat{f}_k = \begin{cases} f_k \Delta x & \text{for } k = 0,\, 1,\, 2,\, \ldots,\, N-1 \\ \widehat{f}_{k+N} & \text{in general} \end{cases} .$$

Facts:

1. [How01, pp. 713–715] Let $\widehat{f}$ be the discrete approximation of a continuous function f based on an Nth order sampling with spacing Δx. Then $\widehat{f}$ is a periodic array of delta functions with spacing Δx and index period N that approximates f over the interval $(0,\, N\Delta x)$. In particular, for any other function ψ which is continuous on $[0,\, N\Delta x]$,

$$\int_0^{N\Delta x} \psi(x) f(x)\, dx \approx \int_0^{N\Delta x} \psi(x) \widehat{f}(x)\, dx = \sum_{k=0}^{N-1} \psi(k\Delta x) \widehat{f}_k \,.$$

Attempting to approximate f with $\widehat{f}$ outside the interval $(0,\, N\Delta x)$, however, cannot be justified unless f is also periodic with period $N\Delta x$.

2. [How01, Chap. 38] Let

$$\mathbf{f} = [f_0,\, f_1,\, f_2,\, \ldots,\, f_{N-1}]^T \qquad \text{and} \qquad \mathbf{F} = [F_0,\, F_1,\, F_2,\, \ldots,\, F_{N-1}]^T$$

be two Nth order sequences, and let

$$f = \sum_{k=-\infty}^{\infty} f_k \delta_{k\Delta x} \qquad \text{and} \qquad F = \sum_{n=-\infty}^{\infty} F_n \delta_{n\Delta\omega}$$

be two corresponding periodic arrays of delta functions with index period N, and with spacings Δx and $\Delta\omega$ satisfying $\Delta x \Delta\omega = 1/N$. Then

$$F = \mathcal{F}[f] \quad \Longleftrightarrow \quad \mathbf{F} = \Delta\omega \sqrt{N}\, \widehat{\mathcal{F}}_N \mathbf{f} \,.$$

In particular, if $\Delta\omega = \Delta x = N^{-1/2}$, then

$$F = \mathcal{F}[f] \quad \Longleftrightarrow \quad \mathbf{F} = \widehat{\mathcal{F}}_N \mathbf{f} \,.$$

3. [How01, pp. 719–723] Suppose f is a continuous, piecewise smooth function that vanishes outside the finite interval $(0, L)$. Let $F = \mathcal{F}[f]$, and let $\widehat{\mathbf{f}}$ be the Nth order scaled sampling of f with spacing Δx chosen so that $L = (N-1)\Delta x$. Then, for each $n \in \mathbb{Z}$,

$$F(n\Delta\omega) \approx \sqrt{N}\, [\widehat{\mathcal{F}}_N \widehat{\mathbf{f}}]_n$$

where $\Delta\omega = (N\Delta x)^{-1}$. The error in this approximation is bounded by

$$(\max|f'| + 2\pi |n| \Delta\omega \max|f|) \frac{L^2 N}{2(N-1)^2} \,.$$

In practice, this bound may significantly overestimate the actual error.

4. [BH95, pp. 181–188] If f is a continuous, piecewise smooth, periodic function with period p and Fourier series $\sum_{n\in\mathbb{Z}} c_n e^{i2\pi\omega_n x}$, then

$$c_n \approx \frac{1}{\sqrt{N}} [\widehat{\mathcal{F}}_N \mathbf{f}]_n \qquad \text{for } -\frac{N}{2} < n \leq \frac{N}{2}$$

where $\mathbf{f}$ is the Nth order sampling of f over $[0, p]$ with spacing $\Delta x = p/N$. Moreover, if f is m-times differentiable on $\mathbb{R}$ and $f^{(m)}$ is piecewise continuous and piecewise monotone for some $m \in \mathbb{N}$, then the error in this approximation is bounded by

$$\frac{\beta}{N^{m+1}}$$

for some positive constant β independent of n and N.

Examples:

1. Let

$$f = \sum_{k=-\infty}^{\infty} f_k \delta_{k/3}$$

be the periodic array with index period $N = 4$ and coefficients

$$f_0 = 0, \quad f_1 = 1, \quad f_2 = 2, \quad \text{and} \quad f_3 = 1\,.$$

The Fourier transform of f is then the periodic array

$$F = \sum_{n=-\infty}^{\infty} F_n \delta_{n\Delta\omega}$$

with index period 4, spacing $\Delta\omega = 3/4$, and coefficients given by

$$\begin{bmatrix} F_0 \\ F_1 \\ F_2 \\ F_3 \end{bmatrix} = \Delta\omega\sqrt{4}\,\widehat{\mathcal{F}}_4\mathbf{f} = \frac{3}{4}\begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & -i & -1 & i \\ 1 & -1 & 1 & -1 \\ 1 & i & -1 & -i \end{bmatrix}\begin{bmatrix} 0 \\ 1 \\ 2 \\ 1 \end{bmatrix} = \frac{1}{2}\begin{bmatrix} 6 \\ -3 \\ 0 \\ -3 \end{bmatrix}.$$

2. The 8th order sampling with spacing $\Delta x = 1/6$ of

$$f(x) = \begin{cases} x & \text{for } 0 \le x \le 1/2 \\ 1 - x & \text{for } 1/2 \le x \le 1 \\ 0 & \text{otherwise} \end{cases}$$

is $\mathbf{f} = [f_0, f_1, f_2, \ldots, f_7]^T$ with

$$f_k = f\left(\frac{k}{6}\right) = \begin{cases} k/6 & \text{for } k = 0, 1, 2, 3 \\ 1 - k/6 & \text{for } k = 4, 5, 6 \\ 0 & \text{for } k = 7 \end{cases}.$$

That is,

$$\mathbf{f} = \left[0, \frac{1}{6}, \frac{2}{6}, \frac{3}{6}, \frac{2}{6}, \frac{1}{6}, 0, 0\right]^T.$$

Multiplying this by the spacing $\Delta x = 1/6$ yields the scaled sampling

$$\widehat{\mathbf{f}} = \left[0, \frac{1}{36}, \frac{2}{36}, \frac{3}{36}, \frac{2}{36}, \frac{1}{36}, 0, 0\right]^T.$$

Letting $F = \mathcal{F}[f]$, $\Delta\omega = (N\Delta x)^{-1} = 3/4$, and $w = e^{-i2\pi/8}$,

$$
\begin{aligned}
F(n\Delta\omega) &\approx \sqrt{8}\,[\widehat{\mathfrak{F}_8}\widehat{\mathbf{f}}]_n \\
&= \frac{1}{36}\left[0w^{0n} + 1w^{1n} + 2w^{2n} + 3w^{3n} + 2w^{4n} + 1w^{5n} + 0w^{6n} + 0w^{7n}\right] \\
&= \frac{1}{36} w^{3n}\left[w^{-2n} + 2w^{-n} + 3 + 2w^{n} + w^{2n}\right],
\end{aligned}
$$

which simplifies to

$$F(n\Delta\omega) \approx \sqrt{8}\,[\widehat{\mathfrak{F}_8}\widehat{\mathbf{f}}]_n = \frac{1}{36}e^{-i3n\pi/4}\left[3 + 2\cos\left(\frac{n\pi}{2}\right) + 4\cos\left(\frac{n\pi}{4}\right)\right].$$

The error bound on this approximation is

$$E_n = (\max|f'| + 2\pi|n|\Delta\omega \max|f|)\frac{L^2 N}{2(N-1)^2} = \frac{4+3\pi|n|}{36}.$$

In fact, the Fourier transform of f is easily found to be

$$F(\omega) = e^{-i\pi\omega}\left[\frac{\sin(\pi\omega/2)}{\pi\omega}\right]^2.$$

So

$$F(n\Delta\omega) = F\left(\frac{3n}{4}\right) = e^{-i3n\pi/4}\left[\frac{4\sin(3n\pi/8)}{3n\pi}\right]^2,$$

and the actual error in the approximation is

$$
\begin{aligned}
\varepsilon_n &= \left|F(n\Delta\omega) - \sqrt{8}\,[\widehat{\mathfrak{F}_8}\widehat{\mathbf{f}}]_n\right| \\
&= \frac{1}{36}\left|64\left[\frac{\sin(n\pi/8)}{n\pi}\right]^2 - 3 - 2\cos\left(\frac{n\pi}{2}\right) - 4\cos\left(\frac{n\pi}{4}\right)\right|.
\end{aligned}
$$

For $n = 0$ through 4, the actual and approximate values of $F(n\Delta\omega)$ (to five decimal places) are

$$
\begin{aligned}
F(0\Delta\omega) &= 0.25000 & \sqrt{8}\,[\widehat{\mathfrak{F}_8}\widehat{\mathbf{f}}]_0 &= 0.25000 \\
F(1\Delta\omega) &= -0.10872(1+i) & \sqrt{8}\,[\widehat{\mathfrak{F}_8}\widehat{\mathbf{f}}]_1 &= -0.11448(1+i) \\
F(2\Delta\omega) &= 0.02252i & \sqrt{8}\,[\widehat{\mathfrak{F}_8}\widehat{\mathbf{f}}]_2 &= 0.02778i \\
F(3\Delta\omega) &= 0.00207(1-i) & \sqrt{8}\,[\widehat{\mathfrak{F}_8}\widehat{\mathbf{f}}]_3 &= 0.00337(1-i) \\
F(4\Delta\omega) &= -0.01126 & \sqrt{8}\,[\widehat{\mathfrak{F}_8}\widehat{\mathbf{f}}]_3 &= -0.02778.
\end{aligned}
$$

The corresponding error bounds and actual errors (to five decimal places) are

$$
\begin{aligned}
E_0 &= 0.11111 & \varepsilon_0 &= 0.00000 \\
E_1 &= 0.37291 & \varepsilon_1 &= 0.00815 \\
E_2 &= 0.63471 & \varepsilon_2 &= 0.00526 \\
E_3 &= 0.89651 & \varepsilon_3 &= 0.00183 \\
E_4 &= 1.15831 & \varepsilon_4 &= 0.01652.
\end{aligned}
$$

Applications:

1. Let f be a continuous, piecewise smooth function to be sampled that is nonzero only in the interval $(0,1)$ and which satisfies

$$|f(x)| \leq \frac{1}{4} \qquad \text{and} \qquad |f'(x)| \leq 1 \qquad \forall\, x \in \mathbb{R}\,.$$

Consider the problem of approximating $F(n\Delta\omega)$ where $F = \mathcal{F}[f]$, $\Delta\omega = 1/2$, and n is any integer from 0 to 10. For each $N \in \mathbb{N}$, set

$$\Delta x = \frac{1}{N\Delta\omega} = \frac{2}{N} \qquad \text{and} \qquad L = (N-1)\Delta x = \frac{2(N-1)}{N},$$

and let $\widehat{\mathbf{f}} = [\widehat{f}_0, \widehat{f}_1, \widehat{f}_2, \ldots, \widehat{f}_{N-1}]^T$ be the corresponding scaled sampling of f,

$$\widehat{f}_k = f(k\Delta x)\Delta x = f\left(\frac{2k}{N}\right) \cdot \frac{2}{N}\,.$$

Then, for $n = 0, 1, 2, \ldots, 10$,

$$F(n\Delta\omega) \approx \sqrt{N}\,[\widehat{\mathcal{F}}_N \widehat{\mathbf{f}}]_n = \frac{2}{N}\sum_{k=0}^{N-1} f\left(\frac{2k}{N}\right) e^{-i2\pi kn/N}$$

with an error bound of

$$(\max|f'| + 2\pi|n|\Delta\omega \max|f|)\frac{L^2 N}{2(N-1)^2} = \frac{4+10\pi}{2N} < \frac{18}{N}\,.$$

2. [CG00, p. 157] (*Deconvolution*) Assume $g = f * h$ where g and h are known by Nth order samplings $\mathbf{g}$ and $\mathbf{h}$, each with spacing Δx. The deconvolution formula for finding f,

$$f = \mathcal{F}^{-1}[V] \qquad \text{where } V = \frac{G}{H} = \frac{\mathcal{F}[g]}{\mathcal{F}[h]}\,,$$

is approximated by

$$f(k\Delta x) \approx \sqrt{N}\left[\widehat{\mathcal{F}}_N^{-1}\widehat{\mathbf{V}}\right]_k$$

where, letting $\Delta\omega = (N\Delta x)^{-1}$, $\widehat{\mathbf{V}}$ is the sequence given by

$$\widehat{V}_n = \Delta\omega \frac{\sqrt{N}\left[\widehat{\mathcal{F}}_N[\widehat{\mathbf{g}}]\right]_n}{\sqrt{N}\left[\widehat{\mathcal{F}}_N[\widehat{\mathbf{h}}]\right]_n} \qquad \text{for } n = 0, 1, 2, \ldots, N-1\,.$$

This reduces to

$$f(k\Delta x) \approx \frac{1}{\Delta x\sqrt{N}}\left[\widehat{\mathcal{F}}_N^{-1}\mathbf{V}\right]_k$$

where, letting $\mathbf{G} = \widehat{\mathcal{F}}_N\mathbf{g}$ and $\mathbf{H} = \widehat{\mathcal{F}}_N\mathbf{h}$,

$$V_n = \frac{G_n}{H_n} \qquad \text{for } n = 0, 1, 2, \ldots, N-1\,.$$

This requires, of course, that each H_n be nonzero.

81.5 The Fast Fourier Transform

A **fast Fourier transform** (**FFT**) is any of a number of algorithms for computing DFTs in which the number of arithmetic computations is greatly reduced through clever use of symmetries and cyclic structures in the DFT matrices. The FFT described here is the standard *radix 2* FFT for computing the Nth order "alternative" discrete Fourier transform $\mathcal{D}_N\mathbf{v}$ given by

$$[\mathcal{D}_N\mathbf{v}]_n = \sqrt{N}[\widehat{\mathcal{F}}_N\mathbf{v}]_n = \sum_{k=0}^{N-1} v_k \, e^{-i2\pi nk/N} .$$

For additional details on implementing a radix 2 FFT and descriptions of other FFTs, see [BH95, Chap. 10], [CG00], or [Wal96].

Facts:

All the following facts, except those with specific references, can be found in [BH95], [CG00], or [Wal96].

1. Two algorithms for computing the alternative DFT $\mathbf{V} = [V_0, V_1, V_2, \ldots, V_{N-1}]^T$ of an Nth order sequence $\mathbf{v} = [v_0, v_1, v_2, \ldots, v_{N-1}]^T$ are given. The first is the "first level" radix 2 FFT illustrating the basic concepts. The second is the more complete radix 2 FFT.

Algorithm 1: *First level radix 2 FFT*
This requires $N = 2M$ for some $M \in \mathbb{N}$:

1. First, split $\mathbf{v}$ into two Mth order sequences $\mathbf{v}^O$ and $\mathbf{v}^E$ composed, respectively, of the even-indexed and odd-indexed elements of $\mathbf{v}$,

   $$\mathbf{v}^E = [v_0^E, v_1^E, v_2^E, \ldots, v_{M-1}^E]^T = [v_0, v_2, v_4, \ldots, v_{2M-2}]^T$$

   and

   $$\mathbf{v}^O = [v_0^O, v_1^O, v_2^O, \ldots, v_{M-1}^O]^T = [v_1, v_3, v_5, \ldots, v_{2M-1}]^T .$$

2. Then compute the Mth order alternative DFTs

   $$[V_0^E, V_1^E, V_2^E, \ldots, V_{M-1}^E]^T = \mathbf{V}^E = \mathcal{D}_N\mathbf{v}^E$$

   and

   $$[V_0^O, V_1^O, V_2^O, \ldots, V_{M-1}^O]^T = \mathbf{V}^O = \mathcal{D}_N\mathbf{v}^O .$$

3. Then construct the Nth order sequence $\mathbf{V} = [V_0, V_1, V_2, \ldots, V_{N-1}]^T$ from $\mathbf{V}^E$ and $\mathbf{V}^O$ via the **butterfly relations**

   $$V_n = \begin{cases} V_n^E + w^n V_n^O & \text{for } n = 0, 1, 2, \ldots, M-1 \\ V_{n-M}^E - w^{n-M} V_{n-M}^O & \text{for } n = M, M+1, M+2, \ldots, N-1 \end{cases}$$

   where $w = e^{-i2\pi/N}$.

Algorithm 2: *Full radix 2 FFT*
This requires $N = 2^P$ for some $P \in \mathbb{N}$. To simplify the description, let

$$\sigma_k \in \begin{cases} \{0\} & \text{if } k = 0 \\ \{E, O\} & \text{if } k = 1,\, 2,\, 3,\, \ldots,\, P \end{cases} .$$

1. Recursively, split $\mathbf{v}$ into the sequences in the set

$$\{\mathbf{v}^{\sigma_0\sigma_1\sigma_2\cdots\sigma_K} \,:\, K = 0, 1, 2, \ldots, P\}$$

where $\mathbf{v}^{\sigma_0} = \mathbf{v}$ and, letting $\Sigma = \sigma_0\sigma_1\sigma_2\cdots\sigma_K$ and $M = 2^{P-K-1}$,

$$\mathbf{v}^{\Sigma E} = \left[v_0^{\Sigma E},\, v_1^{\Sigma E},\, v_2^{\Sigma E},\, \ldots,\, v_{M-1}^{\Sigma E}\right]^T = \left[v_0^{\Sigma},\, v_2^{\Sigma},\, v_4^{\Sigma},\, \ldots,\, v_{2M-2}^{\Sigma}\right]^T$$

and

$$\mathbf{v}^{\Sigma O} = \left[v_0^{\Sigma O},\, v_1^{\Sigma O},\, v_2^{\Sigma O},\, \ldots,\, v_{M-1}^{\Sigma O}\right]^T = \left[v_1^{\Sigma},\, v_3^{\Sigma},\, v_5^{\Sigma},\, \ldots,\, v_{2M-1}^{\Sigma}\right]^T .$$

2. For each of the 2^P first order sequences in $\{\mathbf{v}^{\sigma_0\sigma_1\sigma_2\cdots\sigma_P} = [v^{\sigma_1\sigma_2\cdots\sigma_P}]\}$, set

$$\mathbf{V}^{\sigma_1\sigma_2\cdots\sigma_P} = [V^{\sigma_1\sigma_2\cdots\sigma_P}] = [v^{\sigma_1\sigma_2\cdots\sigma_P}] = \mathbf{v}^{\sigma_1\sigma_2\cdots\sigma_P}$$

3. Set $\mathbf{V} = \mathbf{V}^{\sigma_0}$ where

$$\{\mathbf{V}^{\sigma_0\sigma_1\sigma_2\cdots\sigma_K} \,:\, K = 0, 1, 2, \ldots, P\}$$

is the set of sequences recursively constructed via the **butterfly relations**

$$V_n^{\Sigma} = \begin{cases} V_n^{\Sigma E} + w^n V_n^{\Sigma O} & \text{for } n = 0,\, 1,\, 2,\, \ldots,\, M-1 \\ V_{n-M}^{\Sigma E} - w^{n-M} V_{n-M}^{\Sigma O} & \text{for } n = M,\, M+1,\, M+2,\, \ldots,\, 2M-1 \end{cases}$$

where $\Sigma = \sigma_0\sigma_1\sigma_2\cdots\sigma_K$, $M = 2^{P-K-1}$, and $w = e^{(-i2\pi/N)2^K}$.

2. Let $\mathbf{V}$ be the sequence computed from an Nth order sequence $\mathbf{v}$ by either of the two previous algorithms. Then $\mathbf{V} = \mathcal{D}_N\mathbf{v}$. Multiplying $\mathbf{V}$ by $N^{-1/2}$ yields $\widehat{\mathcal{F}}_N\mathbf{v}$.
3. For corresponding "fast" algorithms for computing the inverse DFT of $\mathbf{v}$, replace $w = e^{-i2\pi/N}$ and $w = e^{(-i2\pi/N)2^K}$, respectively, with $w = e^{i2\pi/N}$ and $w = e^{(i2\pi/N)2^K}$ in the previous algorithms.
4. [BH95, p. 393] Assume $N = 2^P \gg 1$ for some $P \in \mathbb{N}$. Using just the defining formulas, the computation of an Nth order DFT requires approximately $2N^2$ arithmetic operations ($(N-1)^2$ multiplications and $N(N-1)$ additions). Using the above described radix 2 FFT allows this same DFT to be computed with approximately $(3N/2)\log_2 N$ arithmetic operations ($N \log_2 N$ additions and $(N/2)\log_2 N$ multiplications, plus another N multiplications by $N^{-1/2}$ if it is desired to convert the alternative DFT to the one previously described). Thus, the ratio of the number of arithmetic operations used to compute an Nth order DFT by the two methods is

$$\frac{\text{operations if using the FFT}}{\text{operations if not using the FFT}} \approx \frac{3\log_2 N}{4N} .$$

5. Assume $N = 2^P \gg 1$ for some $P \in \mathbb{N}$. Simply using the basic formulas, the compu-

tation of the discrete convolution of two sequences of order N,

$$[\mathbf{v} * \mathbf{w}]_k = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} v_{k-j} w_j ,$$

requires approximately $2N^2$ arithmetic operations ($(N+1)N$ multiplies and $(N-1)N$ additions). On the other hand, this convolution can be computed using the convolution identity

$$\mathbf{v} * \mathbf{w} = \widehat{\mathfrak{F}}_N^{-1}[\mathbf{VW}] \qquad \text{where} \quad \mathbf{V} = \widehat{\mathfrak{F}}_N \mathbf{v} \quad \text{and} \quad \mathbf{W} = \widehat{\mathfrak{F}}_N \mathbf{w} \,.$$

Employing this identity along with the radix 2 FFT to compute the three DFTs involved requires approximately

- $3 \times (3N/2) \log_2 N$ arithmetic operations for the DFTs,
- plus N multiplications for the product $\mathbf{VW}$,

for a total of approximately $(9N/2) \log_2 N$ arithmetic operations. The ratio of operations required to compute this convolution by the two methods is

$$\frac{\text{operations if using identities and the FFT}}{\text{operations if not using identities and the FFT}} \approx \frac{9 \log_2 N}{4N} .$$

Examples:

1. Consider finding the DFT of

$$\mathbf{v} = [v_0,\, v_1,\, v_2,\, v_3]^T = [1,\, 2,\, 3,\, 4]^T$$

using the full radix 2 FFT (Algorithm 2). The order here is $N = 4$ (so $P = 2$). Recursively splitting $\mathbf{v}$ into the even and odd index subsequences yields

$$\mathbf{v}^E = [1,\, 3]^T \qquad \text{and} \qquad \mathbf{v}^O = [2,\, 4]^T$$

and then

$$\mathbf{v}^{EE} = [1], \quad \mathbf{v}^{EO} = [3], \quad \mathbf{v}^{OE} = [2], \quad \text{and} \quad \mathbf{v}^{OO} = [4].$$

(The $\sigma_0 = 0$ superscript is being suppressed.) Setting $\mathbf{V}^{\sigma_1\sigma_2} = \mathbf{v}^{\sigma_1\sigma_2}$ yields

$$\mathbf{V}^{EE} = [1], \quad \mathbf{V}^{EO} = [3], \quad \mathbf{V}^{OE} = [2], \quad \text{and} \quad \mathbf{V}^{OO} = [4].$$

Applying the first round of butterfly relations (in which $K = 1$, $M = 2^{P-K-1} = 1$ and $w = e^{(-i2\pi/4)2^1} = -1$),

$$\begin{aligned}
V_0^E &= V_0^{EE} + w^0 V_0^{EO} = 1 + (-1)^0 3 = 4 \\
V_1^E &= V_0^{EE} - w^{1-1} V_0^{EO} = 1 - (-1)^0 3 = -2 \\
V_0^O &= V_0^{OE} + w^0 V_0^{OO} = 2 + (-1)^0 4 = 6 \\
V_1^O &= V_0^{OE} - w^{1-1} V_0^{OO} = 2 - (-1)^0 4 = -2 \,,
\end{aligned}$$

yields the second order sequences

$$\mathbf{V}^E = [4, -2]^T \qquad \text{and} \qquad \mathbf{V}^O = [6, -2]^T .$$

Applying the second (and last) round of butterfly relations (in which $K = 0$, $M = 2^{P-K-1} = 2$ and $w = e^{(-i2\pi/4)2^0} = -i$),

$$\begin{aligned}
V_0 &= V_0^E + w^0 V_0^O = 4 + (-i)^0 6 = 10 \\
V_1 &= V_1^E + w^1 V_1^O = -2 + (-i)^1(-2) = -2 + 2i \\
V_2 &= V_{2-2}^E - w^{2-2} V_{2-2}^O = 4 - (-i)^0 6 = -2 \\
V_3 &= V_{3-2}^E - w^{3-2} V_{3-2}^O = -2 - (-i)^1(-2) = -2 - 2i\,,
\end{aligned}$$

yields the alternative DFT

$$\mathbf{V} = \mathcal{D}\mathbf{v} = [\,10\,,\ -2+2i\,,\ -2\,,\ -2-2i\,]^T\,.$$

2. Consider the computation of an Nth order DFT. When $N = 1024 = 2^{10}$, the ratio of operations required to compute this DFT with and without using the FFT is

$$\frac{\text{operations if using the FFT}}{\text{operations if not using the FFT}} \approx \frac{3\cdot 10}{4\cdot 2^{10}} \approx 7.3\times 10^{-3}.$$

When $N = 11{,}048{,}576 = 2^{20}$, this ratio is

$$\frac{\text{operations if using the FFT}}{\text{operations if not using the FFT}} \approx \frac{3\cdot 20}{4\cdot 2^{20}} \approx 1.4\times 10^{-5}.$$

3. Consider computing the convolution of two Nth order sequences. When $N = 1024 = 2^{10}$, the ratio of operations required to compute this convolution with and without using the FFT and identities is

$$\frac{\text{operations if using identities and the FFT}}{\text{operations if not using identities and the FFT}} \approx \frac{9\cdot 10}{4\cdot 2^{10}} \approx 2.2\times 10^{-2}.$$

When $N = 11{,}048{,}576 = 2^{20}$, this ratio is

$$\frac{\text{operations if using identities and the FFT}}{\text{operations if not using identities and the FFT}} \approx \frac{9\cdot 20}{4\cdot 2^{20}} \approx 4.3\times 10^{-5}.$$

Many topics taught in an introductory linear algebra course are often motivated by reference to elementary geometry. The geometry is treated as something the student is already familiar with, and reference to it is made to give the student a better understanding of algebraic concepts that may be considered, at least on first acquaintance, to be rather abstract. What is interesting and important is that the process can be reversed: Assuming the linear algebra as known, geometric concepts can be defined and developed on a rigorous basis. The use of vector methods in geometry often provides new ways of looking at old problems and also helps demonstrate deep and beautiful connections between algebra and geometry.

This chapter begins by discussing affine geometry, which can be defined, very roughly, as Euclidean geometry without any mention of measurement. Thus, affine theorems concern such things as incidence and parallelism. An affine space is defined in terms of an action of a vector space V on a set X, pursuant to which a vector $\mathbf{v}$ acts on a point A of X by sending it to another element $\mathbf{v}(A)$ of X, and two points A and B of X define a unique vector $\overrightarrow{AB}$, which acts on A by sending it to B. It might be helpful for the reader to think of $\overrightarrow{AB}$ as an arrow starting at point A and ending at point B. This vector then acts on an arbitrary point C of X by placing the starting point of the arrow at C and letting the end point of the arrow be $\mathbf{v}(C)$.

By introducing an inner product on a real affine space, Euclidean geometry can be defined. Actually, a very interesting mathematical theory can be developed by considering, more generally, an arbitrary bilinear form, but in the interest of simplicity, only (positive definite) real inner products are considered in this chapter. The general theory is discussed in Chapter III of [Art57] and Chapter 2 of [ST91].

Next, projective geometry is considered. Here the points of the geometry are not vectors but one-dimensional subspaces and the resulting incidence properties are different than for Euclidean geometry. Projective geometry plays an important role in (among other things) the mathematical theories of elliptic curves and algebraic geometry, but these topics are far beyond the scope of this chapter.

Finally, hyperbolic spaces are discussed, with particular emphasis on hyperbolic planes. A model of these spaces is given that emphasizes the use of linear algebra (and has applications to physics).

Throughout this chapter, F is a field and V is a finite dimensional vector space over F.

82.1 Affine Spaces

Definitions:

An **affine n-space** is an ordered pair (X,V) where X is a nonempty set and V is an n-dimensional vector space over a field F, which acts on X in the following way: if $\mathbf{v} \in V$ and $A \in X$, then there is an element $\mathbf{v}(A) \in X$, and

1. If **u, v** ∈ V and A∈ X, then $(\mathbf{u} + \mathbf{v})(A) = \mathbf{u}(\mathbf{v}(A))$, and
2. For any two points $A, B \in X$ there exists a unique vector $\mathbf{v} \in V$ such that $\mathbf{v}(A) = B$. This vector $\mathbf{v}$ is denoted $\overrightarrow{AB}$.

The elements of X are called the **points** of the affine space (X, V), and sometimes, when no confusion will result, one speaks of "the affine space X."

A **real affine space** is an affine space (X, V) where V is a vector space over the field $\mathbb{R}$ of real numbers.

If (X, V) is an affine n-space, W is a (vector) subspace of V of dimension $m \le n$, and A is a fixed point in X, then the **affine subspace determined by A and W**, denoted $S(A, W)$, is the set of all points $\mathbf{w}(A)$ as $\mathbf{w}$ ranges over W. A subset of X is called an affine subspace of dimension m if it is of the form $S(A, W)$ for some A in X and subspace W of dimension m (cf. Fact 2, below).

A one-dimensional affine subspace of X is called a **line**; a two-dimensional affine subspace, a **plane**.

The vector subspace W is called the **direction space** of the affine subspace $S(A, W)$.

Two affine subspaces of the same dimension are **parallel** if they have the same direction space. More generally, two affine subspaces (of possibly different dimension) are **parallel** if the direction space of one is a subspace of the direction space of another.

If C is a point in X, the map $P \to \overrightarrow{CP}$ is a bijection between X and V. By identifying a point of X with its image in V under this bijection, addition and scalar multiplication in X can be defined so that it becomes a vector space isomorphic to V, called the **tangent space** at C and denoted $X(C)$.

The elements of a set $\{X_1, \ldots, X_d\}$ of d points in an affine space are **in general position**, or **affine-independent**, if they are not contained in any affine subspace of dimension less than or equal to $d - 2$.

Three points that are affine-independent are called **noncollinear**.

If A and B are distinct points in a real affine space, the set of points P such that $\overrightarrow{AP} = t\overrightarrow{AB}$ for some t, $0 \le t \le 1$, is called the **line segment** from A to B and is denoted $[A, B]$. The point P which corresponds to $t = 1/2$ is the **midpoint** of the line segment.

If A, B, and C are three points in general position in a real affine space, then the set of points P such that $\overrightarrow{AP} = t\overrightarrow{AB} + u\overrightarrow{AC}$, where u and t are nonnegative real numbers whose sum does not exceed 1, is called the **triangl**e with vertices A, B, and C.

A subset Y of a real affine space is **convex** if whenever A and B are in Y, every point on the line segment $[A, B]$ is also in Y.

If (X, V) is an affine n-space and $n \ge 2$, then a bijection $T{:}X \to X$ is **semiaffine** if the image under T of any d-dimensional affine subspace is also a d-dimensional affine subspace, and is **affine** if it is semiaffine and satisfies the following additional condition: If A and B are distinct points and C and D are distinct points, and $\overrightarrow{AB} = k\overrightarrow{CD}$ for some nonzero scalar k, then $\overrightarrow{T(A)T(B)} = k\overrightarrow{T(C)T(D)}$.

If (X, V) is an affine n-space and $\mathbf{v} \in V$, then the translation T_v is the map T_v: $X \to X$ defined by $T_{\mathrm{v}}(A) = \mathbf{v}(\mathbf{A})$.

Facts: For proofs, see [ST71].

1. If A and B are points in an affine space, then
   (a) $\overrightarrow{AB} = \mathbf{0}$ if and only if $A = B$.
   (b) $\overrightarrow{AB} = -\overrightarrow{BA}$.
   (c) $\overrightarrow{AB} + \overrightarrow{BC} = \overrightarrow{AC}$.
2. If $S = S(A, W)$ is an affine subspace of the affine space (X, V), then $W = \{\overrightarrow{AB}\colon A, B \in S\}$. In particular, W is uniquely determined by S.
3. The affine subspaces $S(A, W)$ and $S(B, W)$ are equal if and only if $\overrightarrow{AB} \in W$.
4. The intersection of two affine subspaces is either empty or is an affine subspace. Specifically, if the point P is in both $S(A, U)$ and $S(B, W)$, then $S(A, U) \cap S(B, W) = S(P, U \cap W)$.
5. (Generalized Euclidean Parallel Postulate) If $S = S(A, W)$ is a d-dimensional affine subspace of an affine space X, and P is any point of X, then there exists a unique d-dimensional affine subspace of X, namely $S(P, W)$, that is parallel to S and contains the point P.
6. Given any two distinct points A and B in an affine space, there is a unique line containing them both.
7. The intersection of two convex subsets of a real affine space is convex (possibly empty). In addition, every affine subspace of a real affine space is convex.
8. The set of all semiaffine transformations of an affine n-space (X, V) forms a group under the operation of function composition. The set of all affine transformations of the affine space is a subgroup of this group.
9. A semiaffine transformation of an affine space of dimension at least two maps parallel subspaces to parallel subspaces, i.e., if S and S' are parallel subspaces of the affine space X and T is a semiaffine transformation, then $T(S)$ and $T(S')$ are parallel.
10. If (X, V) is an affine space of dimension at least two and V is a vector space over a field that, like the field of real numbers, has no nontrivial automorphisms, then any semiaffine transformation is an affine transformation.
11. A translation of an affine n-space, where n is at least two, is an affine transformation of that space.
12. If $\{A_0, \ldots, A_n\}$ and $\{B_0, \ldots, B_n\}$ are two sets of points in general position in an affine n-space X, then there is a unique affine transformation T such that $T(A_i) = B_i$ for each $i = 0, 1, \ldots, n$.
13. If C is an arbitrary but fixed point of X and T is an affine transformation of X, then T can be realized as the composition of a mapping that is a nonsingular linear transformation on the tangent space $X(C)$, followed by a translation of X.

Examples:

1. If V is any vector space over a field F, then by taking $X = V$ and $\mathbf{v}(A) = \mathbf{v} + A$ we obtain an affine space, denoted $\mathcal{A}(V)$. For two points (i.e., vectors) A and B, $\overrightarrow{AB} = B - A$. The affine subspaces of $\mathcal{A}(V)$ are precisely the additive cosets of the vector subspaces. When $V = F^n$, the vector space of column n-tuples of elements of a field F, the resulting affine space is often denoted $A^n(F)$.
2. This example, found in [Tar11], shows that two vector spaces, on the same set V and with the same addition, may result in affine spaces of different dimension. Let F be the field $\mathbb{R}(x)$ of real rational functions. We can consider F to be a one-dimensional vector space over itself with scalar multiplication $p(x) \cdot q(x) = p(x)q(x)$. As in Example 1, therefore, F is a one-dimensional affine space with $V = X = F$. We can, on the other hand, also define a

different scalar multiplication on V by taking $p(x) \cdot q(x) = p(x^2)q(x)$. With this definition, F is a two-dimensional vector space over itself with basis $\{1, x\}$ and, hence, a two-dimensional affine space.

3. Any affine subspace $S = \mathbf{v} + W$ of the affine space $\mathcal{A}(V)$ is an affine space (S, W), with $\mathbf{u}(\mathbf{v} + W) = (\mathbf{u} + \mathbf{v}) + W$. It can also be an affine space with a different (but isomorphic) vector space, however. For example, in the affine space $A^2(F)$, let S be the set of all points $\begin{bmatrix} x \\ y \end{bmatrix}$ which satisfy $x + y = 1$, so (S,W) is an affine space with $W = \left\{ \begin{bmatrix} u \\ -u \end{bmatrix} : u \in F \right\}$. But S is also an affine space with associated vector space F, with the action of F on W given by $u \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} x + u \\ y - u \end{bmatrix}$ for $u \in F$.
4. In the affine space $\mathcal{A}(V)$, the tangent space $V(\mathbf{0})$ is identical, not just as a set, but also with regard to the vector space operations, to the vector space V. Fact 13 therefore implies that any affine transformation of this affine space is of the form $T(\mathbf{v}) = L(\mathbf{v}) + \mathbf{b}$, where L is a nonsingular linear transformation from V to itself and $\mathbf{b}$ is a fixed vector.
5. The vectors $\{v_0, \ldots, v_n\}$ in $\mathcal{A}(V)$ are affine-independent if and only if the vectors $\{v_1 - v_0, \ldots, v_n - v_0\}$ are linearly independent in the vector space V. Thus, for example, if $\{\mathbf{u}, \mathbf{v}, \mathbf{w}\}$ and $\{\mathbf{x}, \mathbf{y}, \mathbf{z}\}$ are two sets of vectors in general position in the affine space $\mathcal{A}(V)$, where V is two-dimensional, then to find the unique affine transformation mapping $\mathbf{u}$ to $\mathbf{x}$, $\mathbf{v}$ to $\mathbf{y}$, and $\mathbf{w}$ to $\mathbf{z}$, we first use translation by $-\mathbf{u}$ to map $\{\mathbf{u}, \mathbf{v}, \mathbf{w}\}$ to $\{\mathbf{0}, \mathbf{v} - \mathbf{u}, \mathbf{w} - \mathbf{u}\}$, then use the (unique) linear transformation that maps the linearly independent vectors $\mathbf{v} - \mathbf{u}$ and $\mathbf{w} - \mathbf{u}$ to $\mathbf{y} - \mathbf{x}$ and $\mathbf{z} - \mathbf{x}$, respectively, and finally use translation by $\mathbf{x}$.
6. As a specific illustration of the idea discussed in the previous example, consider $A^2(\mathbb{R})$. Let $\mathbf{u} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}$, $\mathbf{v} = \begin{bmatrix} 2 \\ 1 \end{bmatrix}$, $\mathbf{w} = \begin{bmatrix} 1 \\ 2 \end{bmatrix}$, $\mathbf{x} = \begin{bmatrix} 1 \\ 4 \end{bmatrix}$, $\mathbf{y} = \begin{bmatrix} 4 \\ 7 \end{bmatrix}$, and $\mathbf{z} = \begin{bmatrix} 6 \\ 12 \end{bmatrix}$. If T denotes translation by $\begin{bmatrix} -1 \\ -1 \end{bmatrix}$, then T maps $\mathbf{u}$, $\mathbf{v}$, and $\mathbf{w}$, respectively, to $\mathbf{u}' = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$, $\mathbf{v}' = \begin{bmatrix} 1 \\ 0 \end{bmatrix}$, and $\mathbf{w}' = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$. The linear transformation L that maps $\mathbf{v}'$ and $\mathbf{w}'$ to **y-x** and **z-x** is given by the matrix $\begin{bmatrix} 3 & 5 \\ 3 & 8 \end{bmatrix}$. Thus, the composite transformation LT, which in coordinates is given by $\begin{bmatrix} x \\ y \end{bmatrix} \to \begin{bmatrix} 3x + 5y - 8 \\ 3x + 8y - 11 \end{bmatrix}$, maps $\mathbf{u}$, $\mathbf{v}$, and $\mathbf{w}$ to $\begin{bmatrix} 0 \\ 0 \end{bmatrix}$, $\begin{bmatrix} 3 \\ 3 \end{bmatrix}$, $\begin{bmatrix} 5 \\ 8 \end{bmatrix}$. Composing this composite map with translation by $\begin{bmatrix} 1 \\ 4 \end{bmatrix}$ gives an affine map which maps $\mathbf{u}$, $\mathbf{v}$, $\mathbf{w}$ to $\mathbf{x}$, $\mathbf{y}$, $\mathbf{z}$. In coordinates, this affine map is given by $\begin{bmatrix} x \\ y \end{bmatrix} \to \begin{bmatrix} 3x + 5y - 7 \\ 3x + 8y - 7 \end{bmatrix}$, which can be viewed as $T'L$, where T' is translation by $\begin{bmatrix} -7 \\ -7 \end{bmatrix}$.
7. If $\{2\mathbf{u}, 2\mathbf{v}, 2\mathbf{w}\}$ is a set of three vectors in general position in the affine plane $A^2(\mathbb{R})$, then we can think of these vectors as the vertices of a triangle in the Cartesian plane. (The coefficients appear simply to make subsequent calculations less messy.) The midpoint of the line containing $2\mathbf{u}$ and $2\mathbf{v}$ is $\mathbf{u}+\mathbf{v}$, and similarly for the other sides of the triangle. Thus, the median of the triangle emanating from vertex $2\mathbf{w}$ is the line containing $2\mathbf{w}$ and $\mathbf{u} + \mathbf{v}$, which is the coset $2\mathbf{w} + \text{Span}(\mathbf{u} + \mathbf{v} - 2\mathbf{w})$. It is easy to verify that $(1/3)(\mathbf{2u} + \mathbf{2v} + \mathbf{2w})$ is on this line. Similar calculations show that this point is on the other two medians as well. This gives an algebraic proof of the familiar result from high school geometry that the medians of a triangle are concurrent.
8. Let F be a field that has a nonidentity automorphism f, such as the complex numbers with complex conjugation. In the affine plane $A^2(F)$, the mapping T: $\begin{bmatrix} x \\ y \end{bmatrix} \to \begin{bmatrix} f(x) \\ f(y) \end{bmatrix}$ is a semiaffine transformation that is not affine. To verify that it is not affine, let a be an element

of F that is not fixed by f, and consider the vectors $\mathbf{u} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$, $\mathbf{v} = \begin{bmatrix} 0 \\ a \end{bmatrix}$, $\mathbf{w} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$, and $\mathbf{z} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$. It is then easily verified that $\overrightarrow{\mathbf{uv}} = a(\overrightarrow{\mathbf{wz}})$ but $\overrightarrow{T(\mathbf{u})T(\mathbf{v})} = f(a)\overrightarrow{T(\mathbf{w})T(\mathbf{z})}$.

82.2 Euclidean Spaces

Definitions:

Euclidean n-space is an affine n-space (X, V) where V is a real inner product space. When $n = 2$, Euclidean n-space is called a **Euclidean plane**.

The **distance** between two points A and B in the Euclidean n-space (X, V) is $||\overrightarrow{AB}||$, where the norm is taken pursuant to the inner product in V. This distance is denoted $d(A, B)$.

Two lines in a Euclidean plane are **orthogonal** if the vectors that span their respective direction spaces are orthogonal with respect to the inner product of V.

If A and B are distinct points in a Euclidean plane, the **perpendicular bisector** of line segment $[A, B]$ is the line passing through the midpoint of this segment whose direction space is the orthogonal complement of the space spanned by the vector $\overrightarrow{AB}$.

An **isometry** or **rigid motion** of a Euclidean n-space (X, V) is a bijection T of X that preserves distances: $d(A, B) = d(T(A), T(B))$, for all A and B in X.

The **linear transformation associated with** T is the mapping $T'{:}V \to V$ defined by $T'(\overrightarrow{AB}) = \overrightarrow{T(A)T(B)}$ (cf. Fact 4, below).

The isometry T is **direct** if T' has positive determinant, **indirect** if T' has negative determinant.

The remaining definitions in this section apply to the Euclidean plane $A^2(\mathbb{R})$ with the ordinary dot product as the inner product. (Recall from the preceding section that this is the affine plane obtained by taking $X = V = \mathbb{R}^2$.)

A 2 × 2 **rotation matrix** is a matrix of the form $R_\theta = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix}$.

A 2 × 2 **reflection matrix** is a matrix of the form $S_\theta = \begin{bmatrix} \cos\theta & \sin\theta \\ \sin\theta & -\cos\theta \end{bmatrix}$.

If C is a fixed point in $\mathbb{R}^2$, a **rotation about point C** is a mapping from $\mathbb{R}^2$ to itself of the form $T(X) = R_\theta(X - C) + C$, for some 2 × 2 rotation matrix R_θ.

If l is a line, the **reflection through** l is the mapping from $A^2(\mathbb{R})$ to itself which sends every point on l to itself, and which sends a point C not on l to the unique point C' with the property that l is the perpendicular bisector of the line segment $[C, C']$.

A **glide reflection** is a reflection through a line l followed by translation by a nonzero vector that spans the direction space of l.

Facts: For proofs, see [Roe93] and [Ree83].

1. The distance function d on a Euclidean n-space is a metric on the set X. Specifically, this means that if A, B, and C are arbitrary points of X, then
   (a) $d(A,\ B)$ is nonnegative, and equal to 0 if and only if $A = B$.
   (b) $d(A,\ B) = d(B,\ A)$.
   (c) $d(A,\ B) \leq d(A{,}C) + d(C,\ B)$.
2. The point C is in the line segment $[A, B]$ if and only if $d(A, C) + d(C, B) = d(A, B)$.
3. (Pythagorean Theorem) If A, B, and C are three noncollinear points in a Euclidean n-space and $\overrightarrow{AB}$ is orthogonal to $\overrightarrow{BC}$, then $d(A, B)^2 + d(B, C)^2 = d(A, C)^2$.
4. An isometry is an affine mapping.

5. The associated linear transformation of an isometry is a well-defined orthogonal linear transformation.
6. In the Euclidean space $A^n(\mathbb{R})$, when an isometry is written as $T(\mathbf{v}) = \mathbf{L}(\mathbf{v}) + \mathbf{b}$ for a nonsingular linear transformation L and vector $\mathbf{b}$, the associated linear transformation T' is simply L. (Such an expression for an isometry T is always possible.)
7. Any translation in a Euclidean n-space is an isometry of that space. The associated linear transformation of a translation is the identity map.
8. The set of all isometries of a Euclidean space (X, V) is a group (under the operation of function composition).
9. The map that associates to every isometry T its associated linear transformation T' is a homomorphism from the isometry group onto the group of all orthogonal linear transformations of V, the kernel of which is the set of all translations.
10. If l is a line in the affine space $A^2(\mathbb{R})$, then reflection through l is an isometry.
11. If l is a line that passes through the origin in $A^2(\mathbb{R})$, then reflection through l is a linear transformation given by a reflection matrix. Conversely, the linear transformation defined by multiplication of a vector by a (fixed) reflection matrix S_θ is a reflection through the line passing through the origin with direction space spanned by $\begin{bmatrix}\cos(\theta/2)\\ \sin(\theta/2)\end{bmatrix}$.
12. A rotation is an isometry.
13. In $A^2(\mathbb{R})$, a rotation about the origin $\mathbf{0}$ is a linear transformation given by a rotation matrix.
14. In $A^2(\mathbb{R})$, the point C is the unique fixed point of a nonidentity rotation about C. Any isometry with a unique fixed point is a rotation.
15. Any isometry of $A^2(\mathbb{R})$ can be written as the product of three or fewer reflections.
16. Every isometry of $A^2(\mathbb{R})$ is either a translation, rotation, reflection, or glide reflection.
17. In $A^2(\mathbb{R})$, the product of a reflection with itself is the identity mapping. The product of two distinct reflections is a translation if the reflections are through parallel lines; if the reflections are through two lines intersecting at a point, the product of the two reflections is a rotation about that point. The product of three reflections is either a reflection or glide reflection.
18. The translations and rotations are the direct isometries of $A^2(\mathbb{R})$ and the reflections and glide reflections are the indirect ones.
19. Two triangles ABC and $A'B'C'$ in $A^2(\mathbb{R})$ are congruent in the sense of high school geometry (i.e., corresponding sides and angles are equal) if and only if there is an isometry of $A^2(\mathbb{R})$, which maps A to A', B to B', and C to C'.

Examples:

1. In $A^2(\mathbb{R})$, the line segment between $\begin{bmatrix}1\\1\end{bmatrix}$ and $\begin{bmatrix}3\\3\end{bmatrix}$ lies on a line with direction space spanned by $\begin{bmatrix}1\\1\end{bmatrix}$; the span of $\begin{bmatrix}-1\\1\end{bmatrix}$ is the orthogonal complement of this direction space. The midpoint of this line segment is $\begin{bmatrix}2\\2\end{bmatrix}$. Therefore, the perpendicular bisector of this segment is the line l given by $\begin{bmatrix}2\\2\end{bmatrix} + \text{Span}\left(\begin{bmatrix}-1\\1\end{bmatrix}\right)$.
2. In $A^2(\mathbb{R})$ the map $\begin{bmatrix}x\\y\end{bmatrix} \to \begin{bmatrix}-y\\-x\end{bmatrix}$ has matrix $\begin{bmatrix}0 & -1\\-1 & 0\end{bmatrix}$, which is a reflection matrix. To determine the line through which this mapping is a reflection, note that its eigenvalues are 1 and -1. An eigenvector for the eigenvalue 1 is $\begin{bmatrix}1\\-1\end{bmatrix}$. Thus, the line spanned by $\begin{bmatrix}1\\-1\end{bmatrix}$ is

the line through which this mapping reflects. Alternatively, $\begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix} = S_{3\pi/2}$, so by Fact 11, the line of reflection is spanned by $\begin{bmatrix} \cos(3\pi/4) \\ \sin(3\pi/4) \end{bmatrix} = \begin{bmatrix} -1/\sqrt{2} \\ 1/\sqrt{2} \end{bmatrix}$.

3. The mapping $\begin{bmatrix} x \\ y \end{bmatrix} \rightarrow \begin{bmatrix} -y \\ x \end{bmatrix}$ has matrix $\begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$, which is a rotation matrix (corresponding to $\theta = \pi/2$). The mapping T: $\begin{bmatrix} x \\ y \end{bmatrix} \rightarrow \begin{bmatrix} -y+1 \\ x \end{bmatrix}$, which is a direct isometry and not a translation, must correspond to a rotation also, through a point other than the origin. To determine the center of this rotation, we compute the unique fixed point to be $x = 1/2 = y$. Thus, T is a rotation around the point $\begin{bmatrix} 1/2 \\ 1/2 \end{bmatrix}$.

82.3 Projective Spaces

Definitions:

If V is an $(n+1)$-dimensional vector space over a field F, then the **n-dimensional projective space based on** V, denoted $\mathcal{P}(V)$, is the set of all subspaces of V. The one-dimensional subspaces of V are the **points** of $\mathcal{P}(V)$; the two-dimensional subspaces of V are the **lines** of $\mathcal{P}(V)$. More generally, the **k-dimensional projective subspaces** are the $(k+1)$-dimensional subspaces of V.

When V has dimension 3, $\mathcal{P}(V)$ is called the **projective plane** based on V.

A point Span($\mathbf{v}$) **lies on** a projective subspace if it is a subset of that projective subspace.

Relative to a fixed ordered basis of V, any nonzero element of V can be identified with an $(n+1)$-tuple of elements of F. Thus, by selecting a spanning vector of any point of $\mathcal{P}(V)$, that point can be identified with an $(n+1)$-tuple of elements of F, where not all of the components are zero and where two such $(n+1)$-tuples are identified if one is a nonzero scalar multiple of the other. Under this identification, the $(n+1)$-tuple is denoted $[a_1\colon a_2\colon \dots : a_{n+1}]$ and called the **homogeneous coordinates** of the point. (In many geometry books, homogenous coordinates are denoted $[a_1, a_2, \dots, a_{n+1}]$, but here that notation risks confusion with a $1 \times n$ matrix.)

When $\mathcal{P}(\mathcal{V})$ is a projective space of dimension n, with ordered basis $\mathcal{B}$ for V, then for any r-dimensional subspace W of V there is an $(n+1-r)$-dimensional subspace of the dual space V^* consisting of those linear functionals of V that vanish on W (cf. Section 3.8). In particular, if $\mathcal{P}(\mathcal{V})$ is a projective plane, then points (respectively, lines) of $\mathcal{P}(\mathcal{V})$ correspond to lines (respectively, points) of $\mathcal{P}(\mathcal{V}^*)$. Since, relative to the dual basis of V^*, any point can be given homogenous coordinates, any line of $\mathcal{P}(\mathcal{V})$ can be given the homogenous coordinates of its annihilator; these are **homogenous line coordinates.**

The **dual** of a statement concerning points and lines in a projective plane is the statement obtained by interchanging the terms "point" and "line."

If $\{A, B, C\}$ and $\{A', B', C'\}$ are two sets of noncollinear points in a projective plane $\mathcal{P}(V)$, then the triangles ABC and $A'B'C'$ are **perspective from the point** P if and only if the lines containing A and A', B and B', and C and C' all pass through the point P.

The triangles ABC and $A'B'C'$ are **perspective from the line** l if the points of intersection of the corresponding sides of the triangles all lie on the line l.

If T is a nonsingular linear transformation of V, then the mapping $\hat{T}$ from $\mathcal{P}(V)$ to itself, defined by mapping Span($\{\mathbf{v}_1, \dots, \mathbf{v}_m\}$) to Span$\{T(\mathbf{v}_1), \dots, T(\mathbf{v}_m)\}$, is called the **projective transformation** (or **projectivity**) **determined by T.**

A **collineation** of $\mathcal{P}(V)$ is a bijective mapping from $\mathcal{P}(V)$ onto itself which maps subspaces to subspaces of the same dimension and which preserves set inclusion.

Facts: For proofs see [Kap69] or specific references.

1. In a projective plane $\mathcal{P}(V)$, points and lines satisfy the following incidence properties:
   (a) Two distinct points A and B lie on a unique line, denoted AB.
   (b) Two distinct lines meet in a unique point.
   (c) There are four distinct points, no three of which are collinear.
2. In the projective plane $\mathcal{P}(\mathcal{V})$, the dual of any theorem involving the incidence of points and lines is also a theorem. (In the preceding fact, for example, statement (b) is the dual of statement (a), and vice versa.)
3. [Art57] Any projective transformation of the projective space $\mathcal{P}(\mathcal{V})$ is a collineation of $\mathcal{P}(\mathcal{V})$. If F is a field that does not have any nontrivial automorphisms (such as, for example, the field of real numbers), then any collineation of the projective space $\mathcal{P}(\mathcal{V})$ is a projective transformation.
4. In the projective plane $\mathcal{P}(\mathcal{V})$, if a point P has homogenous coordinates $[a{:}\ b{:}\ c]$ and a line l has homogenous coordinates $[x{:}\ y{:}\ z]$, then P lies on l if and only if $ax+by+cz=0$. Thus, to find the homogenous line coordinates of the line containing the points $[a{:}\ b{:}\ c]$ and $[d{:}\ e{:}\ f]$, we can use the formula for vector cross product to find a vector $\begin{bmatrix} x \\ y \\ z \\ R12 \end{bmatrix}$, which is orthogonal to the two vectors $\begin{bmatrix} a \\ b \\ c \end{bmatrix}$ and $\begin{bmatrix} d \\ e \\ f \end{bmatrix}$ under the usual dot product. For an arbitrary field F, this formula yields the homogenous line coordinates $[x{:}\ y{:}\ z]$ of the line containing the two points.
5. (Desargues' Theorem and its converse) Two triangles in a projective plane $\mathcal{P}(\mathcal{V})$ are perspective from a point if and only if they are perspective from a line.
6. (Pappus' Theorem) Let A, B, C and A', B', C' be two triples of distinct collinear points in a projective plane. Let P, Q, and R denote, respectively, the points of intersection of the lines AB' and $A'B$, AC' and $C'A$, and BC' and $B'C$. Then P, Q, and R are collinear.
7. Let A, B, C, and D be four distinct points in a projective plane $\mathcal{P}(\mathcal{V})$ with the property that no three are collinear. Let A', B', C', and D' be four other distinct points with this property. Then there is a unique projective transformation which maps A to A', B to B', C to C', and D to D'.

Examples:

1. If V is a two-dimensional vector space over the field of complex numbers, then the projective line $\mathcal{P}(\mathcal{V})$ can be realized as the set of all homogeneous coordinates $[x{:}\ y]$ where x and y are complex numbers, not both zero. By identifying $[x{:}\ y]$ with the complex number x/y if y is nonzero, and with ∞ if $y = 0$, we can identify $\mathcal{P}(\mathcal{V})$ with the extended complex plane studied in courses on complex analysis. Note also that the complex-linear transformation of V given by a nonsingular matrix $\begin{bmatrix} a & b \\ c & d \end{bmatrix}$ represents the mapping of the extended plane given by $z \mapsto \dfrac{az+b}{cz+d}$; these are the linear fractional transformations studied in such a course.
2. The smallest projective space of dimension greater than 1 is obtained by letting V be a three-dimensional vector space over the two-element field Z_2. In homogenous coordinates, every element of $\mathcal{P}(\mathcal{V})$ is represented by a triple $[a{:}\ b{:}\ c]$ where each entry is either 0 or 1 and not all entries are 0. Thus, there are seven points in this projective plane, and by duality

there are seven lines as well. It is easy to verify that each line of this projective plane consists of three points, and each point is contained on three lines. For example, the line containing the points [1: 1: 1] and [1: 0: 0], obtained by taking the span of these vectors, contains these points, the point with homogenous coordinates [0: 1: 1], and no other points (i.e., no other nonzero vector spans a one-dimensional subspace of the span of these two points).

3. If V is a three-dimensional vector space over the field of real numbers, then, thinking of the points of $\mathcal{P}(\mathcal{V})$ in terms of homogenous coordinates relative to a given fixed ordered basis of V, the points [0: 1: 0] and [0: 0: 1] lie on a unique line, which is the span of these vectors (i.e., the two-dimensional subspace of V consisting of all points with homogenous coordinates with first component zero). In the dual space of V, relative to the dual basis of the given ordered basis of V, this subspace corresponds to the subspace of all linear functionals of V that annihilate all such vectors. This is clearly the span of the first vector in the ordered dual basis. Thus, the homogenous line coordinates for the line containing the two given points is [1: 0: 0]. This can also be obtained as a cross product.
4. To illustrate Pappus' Theorem, let six points be given as follows in the real projective plane: A = [1: 0: 0], B = [0: 1: 0], C = [1: 1: 0], A' = [1: 1: 2], B' =[1: 2: 2], C' = [0: 0: 1]. It was observed above that the line BC' consists of all points with homogenous coordinates with first component zero. It is easy to see that the line containing C and B' is the set of triples of real numbers of the form $\begin{bmatrix} a+b \\ a+b \\ a \end{bmatrix}$. The intersection of these two lines is obtained by letting $a = -b$, and, therefore, is the point with homogenous coordinates [0: 0: 1]. By similar calculations, the intersection of the lines AB' and $A'B$ is seen to be the point with homogenous coordinates [1: 2: 2] and the intersection of the lines CA' and $C'A$ is the point with homogenous coordinates [0: 0: 1]. Since the vectors $\begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}$, $\begin{bmatrix} 1 \\ 2 \\ 2 \end{bmatrix}$, and $\begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}$ are linearly dependent, the one-dimensional subspaces spanned by these vectors are collinear points, as required by Pappus' Theorem.
5. The three incidence relations described in Fact 1 are usually taken as the defining relations for an axiomatic definition of projective plane, in which "point," "line," and "incidence" are taken as undefined notions. It is not the case that any projective plane defined axiomatically in this way is of the form $\mathcal{P}(\mathcal{V})$ for some vector space V over a field F. As an example, if we interpret "point" to mean the set of all ordered pairs of real numbers and "line" to mean any horizontal Euclidean line, vertical Euclidean line, Euclidean line of negative slope, or broken Euclidean line of positive slope m above the x-axis and slope $2m$ below the x-axis, we obtain a geometric system that satisfies the standard incidence relations for points and lines, and the Euclidean parallel postulate. We can convert this example into a projective plane by the addition of "ideal points": To every line we add a new point, with the same point being added to two lines if and only if they are parallel. We also add a new line consisting of the ideal points, and no other points. The augmented geometric system satisfies the axioms of a projective plane, but neither Desargues' Theorem nor Pappus' Theorem holds in this plane. (This example is called the *Moulton Plane.*)
6. The addition of ideal points, as in the preceding example, can be carried out in any affine plane $A^2(F)$. An affine point $\begin{bmatrix} a \\ b \end{bmatrix}$ can be identified with the projective point with homogenous coordinates [a: b: 1] and the ideal points are those with homogenous coordinates with a zero in the third component.
7. In a projective n-space $\mathcal{P}(\mathcal{V})$, let H be a subspace of V of dimension n. Starting from an ordered basis for H, obtain an ordered basis for V by adding a single vector as the last element of the basis. Then, in homogenous coordinates, every point of $\mathcal{P}(V\ )$ that is not

in H has nonzero last component. By associating the point with homogenous coordinates $[a_1\colon \dots : a_{n+1}]$ with the n-tuple $\begin{bmatrix} \frac{a_1}{a_{n+1}} \\ \vdots \\ \frac{a_n}{a_{n+1}} \end{bmatrix}$ we can think of the set of points that are not in H as the affine n-space $A^n(F)$.

8. Let $\mathcal{P}(\mathcal{V})$ be a projective plane, where V is a vector space over a field F that has a nonidentity automorphism f. The mapping $[a\colon b\colon c] \mapsto [f(a)\colon f(b)\colon f(c)]$ is a collineation. Since this mapping fixes the points [0: 0: 1], [0: 1: 0], [1: 0: 0], and [1: 1: 1] and is not the identity, it cannot, by Fact 7, be a projective transformation.
9. In the real projective plane, consider the six points $A = [1\colon 2\colon 1]$, $B = [2\colon 0\colon 1]$, $C = [5 :5 :1]$, $A' = [2\colon 4\colon 1]$, $B' = [4\colon 0\colon 1]$, and $C' = [10\colon 10\colon 1]$. Identifying the projective point with homogenous coordinates $[a\colon b\colon 1]$ with the ordinary Euclidean point $\begin{bmatrix} a \\ b \end{bmatrix}$, as in Example 6, it can be seen by a simple diagram that the triangles ABC and $A'B'C'$ are perspective from the origin, since all lines AA', BB', and CC' pass through this point. Thus, in the real projective plane these triangles are perspective from the point [0: 0: 1]. Desargues' Theorem, therefore, asserts that the points of intersection of the lines AB and $A'B'$, AC and $A'C'$, BC and $B'C'$ will lie on a line. A simple calculation shows that these three points, in homogenous coordinates, have third component zero, so these points are indeed collinear. This corresponds to the fact that as Euclidean lines there are no points of intersection — the corresponding sides of the triangles are parallel in pairs. The points with third component zero are the "ideal points" that have been added to Euclidean geometry to form the real projective plane.

82.4 Hyperbolic Spaces

Definitions:

The **Lorentz form** on $\mathbb{R}^{n+1}$ is the bilinear form b defined as follows: if $\mathbf{x}=\begin{bmatrix} x_1 \\ \vdots \\ x_n \\ x_{n+1} \end{bmatrix}$ and $\mathbf{y}=\begin{bmatrix} y_1 \\ \vdots \\ y_n \\ y_{n+1} \end{bmatrix}$ then $b(\mathbf{x},\mathbf{y}) = x_1y_1+x_2y_2+...+x_ny_n-x_{n+1}y_{n+1}$. The **Lorentz quadratic form** is the quadratic form q associated with $b : q(\mathbf{x}) = b(\mathbf{x},\mathbf{x})$. An element $\mathbf{x}$ of $\mathbb{R}^{n+1}$ is **spacelike** if $q(\mathbf{x}) > 0$, **timelike** if $q(\mathbf{x}) < 0$, and **lightlike** if $q(\mathbf{x}) = 0$, and is a **unit vector** if $q(\mathbf{x}) = 1$.

Hyperbolic n-dimensional space $\mathbb{H}^n$ is the subset of $\mathbb{R}^{n+1}$ consisting of all vectors $\mathbf{x}=\begin{bmatrix} x_1 \\ \vdots \\ x_{n+1} \end{bmatrix}$ such that $q(\mathbf{x}) = -1$ and $x_{n+1} > 0$. When $n = 2$, $\mathbb{H}^2$ is called the **hyperbolic plane**.

A **point** is an element of $\mathbb{H}^n$. A **line** is a non-empty subset of $\mathbb{H}^n$ which can be written as the intersection of $\mathbb{H}^n$ with a two-dimensional vector subspace of $\mathbb{R}^{n+1}$. In the hyperbolic plane $\mathbb{H}^2$, any line can be written as $\{\mathbf{x} \in \mathbb{H}^2 : b(\boldsymbol{\xi},\mathbf{x}) = 0\}$ for some unit spacelike vector $\boldsymbol{\xi}$: this vector $\boldsymbol{\xi}$ is the **pole** or **unit normal** of the line.

The **Lorentz cross product** of two vectors $\mathbf{u}$ and $\mathbf{v}$ in $\mathbb{R}^3$, denoted $\mathbf{u}\times_L\mathbf{v}$, is obtained by computing the ordinary cross product of $\mathbf{u}$ and $\mathbf{v}$ and then changing the sign of the third component. In terms of matrices, $\mathbf{u}\times_L\mathbf{v}= \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{bmatrix} \mathbf{u}\times\mathbf{v}$.

Two lines l and m in $\mathbb{H}^2$, with respective unit normals $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$, are called **parallel** if $\boldsymbol{\xi} \times_L \boldsymbol{\eta}$ is lightlike and **ultraparallel** if $\boldsymbol{\xi} \times_L \boldsymbol{\eta}$ is spacelike. These lines are called **intersecting** if $\boldsymbol{\xi} \times_L \boldsymbol{\eta}$ is timelike. These lines are **perpendicular** if $b(\boldsymbol{\xi}, \boldsymbol{\eta}) = 0$.

The **distance between two points x** and **y** in $\mathbb{H}^n$ is defined as $d(\mathbf{x}, \mathbf{y}) = \cosh^{-1}(-b(\mathbf{x}, \mathbf{y}))$, where cosh denotes, as usual, the hyperbolic cosine function. A function $T : \mathbb{H}^n \to \mathbb{H}^n$ is called an **isometry** if for all $\mathbf{x}$, $\mathbf{y} \in \mathbb{H}^n$, we have $d(T\mathbf{x}, T\mathbf{y}) = d(\mathbf{x}, \mathbf{y})$.

If α is a line in the hyperbolic plane $\mathbb{H}^2$ with unit normal $\boldsymbol{\xi}$, the function $\Omega_\alpha : \mathbb{H}^2 \to \mathbb{H}^2$ defined by $\Omega_\alpha \mathbf{x} = \mathbf{x} - 2b(\mathbf{x}, \boldsymbol{\xi})\boldsymbol{\xi}$ is called the **reflection in the line $\boldsymbol{\alpha}$**. If α and β are lines that both contain a point P, then the map $\Omega_\alpha\Omega_\beta$ is called a **rotation about P**. If α and β are parallel, then $\Omega_\alpha\Omega_\beta$ is called a **parallel displacement**. If α and β are ultraparallel with common perpendicular l, then $\Omega_\alpha\Omega_\beta$ is called the **translation along $\boldsymbol{l}$**. A **glide reflection** in $\mathbb{H}^2$ is the product of a reflection in line l with a translation along l.

Facts: For proofs, see [Rya86] and [RS05].

1. If P and Q are distinct points in $\mathbb{H}^n$, then there is a unique line containing P and Q.
2. Intersecting lines, with unit normals $\boldsymbol{\xi}$ and $\boldsymbol{\eta}$, in $\mathbb{H}^2$, have exactly one point in common, namely the unique point in $\mathbb{H}^2$ that is a multiple of $\boldsymbol{\xi} \times_L \boldsymbol{\eta}$.
3. Two lines in the hyperbolic plane $\mathbb{H}^2$ are ultraparallel if and only if they have a common perpendicular.
4. Given a line l in the hyperbolic plane and a point P not on l, there are infinitely many lines through P that do not intersect l. Two of these lines are parallel to l and all the others are ultraparallel to l (the intuitive picture is that the two parallel lines form a region in which all the ultraparallel lines are trapped).
5. The distance function d is a metric on the set $\mathbb{H}^n$: $d(\mathbf{x}, \mathbf{y}) \geq 0$ and is equal to 0 when and only when $\mathbf{x}$=$\mathbf{y}$; d($\mathbf{x}$,$\mathbf{y}$)=d($\mathbf{y}$,$\mathbf{x}$) for all $\mathbf{x}$, $\mathbf{y} \in \mathbb{H}^n$, and d($\mathbf{x}$,$\mathbf{y}$)$\leq$ d($\mathbf{x}$,$\mathbf{z}$)+d($\mathbf{z}$,$\mathbf{y}$) for all $\mathbf{x}$, $\mathbf{y}$, $\mathbf{z} \in \mathbb{H}^n$.
6. Every reflection is an isometry of the hyperbolic plane $\mathbb{H}^2$. Since every product of isometries is obviously an isometry, it follows that every rotation, parallel displacement, translation, and glide reflection is an isometry as well. These are all the isometries of the hyperbolic plane.

Examples:

1. The vector $\begin{bmatrix}1\\0\\0\end{bmatrix}$ is spacelike, the vector $\begin{bmatrix}1\\0\\1\end{bmatrix}$ is lightlike, and the vector $\begin{bmatrix}0\\0\\1\end{bmatrix}$ is timelike (and an element of $\mathbb{H}^2$).
2. The set of all vectors $\begin{bmatrix}x\\y\\z\end{bmatrix}$ in $\mathbb{H}^2$ that have $y = 0$ is the intersection of $\mathbb{H}^2$ with the two-dimensional subspace of $\mathbb{R}^3$ spanned by $\begin{bmatrix}1\\0\\0\end{bmatrix}$ and $\begin{bmatrix}0\\0\\1\end{bmatrix}$, and hence is a line in $\mathbb{H}^2$. The unit normal (or pole) of this line is the vector $\begin{bmatrix}0\\1\\0\end{bmatrix}$.
3. Let l be the line in the previous example and P the point $\begin{bmatrix}0\\1\\\sqrt{2}\end{bmatrix}$, which is not on l. We will exhibit two lines through P that are parallel to l and infinitely many that are ultraparallel. Note that any line m through P has unit normal of the form $\begin{bmatrix}x\\\sqrt{2}z\\z\end{bmatrix}$ where $x^2 + z^2 = 1$ (the

last condition follows from the fact that it is a unit vector). Thus, any unit normal for a line m through P is of the form $\xi_\theta = \begin{bmatrix} \cos\theta \\ \sqrt{2}\sin\theta \\ \sin\theta \end{bmatrix}$. Computing the Lorentz cross product of ξ_θ and $\begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}$ (the unit normal for line l) we see that m is parallel to l if and only if $\cos\theta = \pm\sin\theta$ and ultraparallel if and only if $\sin^2\theta > \cos^2\theta$.

4. The hyperbolic distance between the points $\begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}$ and $\begin{bmatrix} 2 \\ 2 \\ 3 \end{bmatrix}$ is $\cosh^{-1}(3)$, which is approximately 1.7627. The Euclidean distance between these points is, of course, $\sqrt{12}$ or approximately 3.464.
5. [Rya86] Let $\mathbf{P}$ be any point of $\mathbb{H}^2$. Choose vectors $\boldsymbol{e_1}$ and $\boldsymbol{e_2}$ so that the three vectors $\boldsymbol{e_1}$, $\boldsymbol{e_2}$, and $\mathbf{P}$ are orthonormal with respect to b. Then if α is any line through $\mathbf{P}$, the unit normal $\boldsymbol{\xi}$ of α can be written as $\boldsymbol{\xi} = (-\sin\theta)\boldsymbol{e_1} + (\cos\theta)\boldsymbol{e_2}$. It follows that $\Omega_\alpha(\boldsymbol{e_1}) = \boldsymbol{e_1} - 2(-\sin\theta)\boldsymbol{\xi} = (\cos 2\theta)\boldsymbol{e_1} + (\sin 2\theta)\boldsymbol{e_2}$, $\Omega_\alpha(\boldsymbol{e_2}) = \boldsymbol{e_2} - (2\cos\theta)\boldsymbol{\xi} = (\sin 2\theta)\boldsymbol{e_1} - (\cos 2\theta)\boldsymbol{e_1}$, and $\Omega_\alpha(\mathbf{P}) = \mathbf{P}$. Thus, the matrix of Ω_α relative to the basis $\{\boldsymbol{e_1}, \boldsymbol{e_2}, \mathbf{P}\}$ is $\begin{bmatrix} \cos 2\theta & \sin 2\theta & 0 \\ \sin 2\theta & -\cos 2\theta & 0 \\ 0 & 0 & 1 \end{bmatrix}$.
6. (Continuation of previous example). Suppose that β is another line through $\mathbf{P}$, with unit normal $\boldsymbol{\eta} = (-\sin\phi)\boldsymbol{e_1} + (\cos\phi)\boldsymbol{e_2}$. Then the matrix of the rotation $\Omega_\alpha\Omega_\beta$ is (using familiar trigonometric identities) $\begin{bmatrix} \cos 2(\theta-\phi) & -\sin 2(\theta-\phi) & 0 \\ \sin 2(\theta-\phi) & \cos 2(\theta-\phi) & 0 \\ 0 & 0 & 1 \end{bmatrix}$. The 2×2 upper-left block matrix is the matrix of the ordinary Euclidean rotation about $\mathbf{P}$ with angle $2(\theta - \phi)$.

This chapter presents some facts and examples illustrating the interplay between matrix theory, graph theory, and n-dimensional Euclidean geometry. A recent global reference on the topic is the book [Fie11].

83.1 Euclidean Point Space

Definitions:

An **arithmetic Euclidean vector space** is the real inner product space $\mathbb{R}^n$ with the standard inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \mathbf{y}^T \mathbf{x}$.

The **arithmetic point Euclidean** n**-space** E^n based on the vector space $\mathbb{R}^n$ has as **points** the column $n+1$-tuples with last coordinate 1, e.g., $\mathbf{C} = [c_1, c_2, \dots, c_n, 1]^T$, and as **vectors** the column $n+1$-tuples with last coordinate 0, e.g., $\mathbf{v} = [v_1, v_2, \dots, v_n, 0]^T$.

The origin $\mathbf{O}$ is the point $[0, \dots, 0, 1]^T$; the numbers $c_1, \dots, c_n$ are **coordinates** of the point $\mathbf{C}$.

Algebraic operations are defined with points: If $\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_m$ are points, $a_1, a_2, \dots, a_m$ real numbers, then the symbol

$$a_1\mathbf{A}_1 + a_2\mathbf{A}_2 + \cdots + a_m\mathbf{A}_m$$

means a **point** if and only if $\sum a_k = 1$, and a **vector** if and only if $\sum a_k = 0$. In no other case is this symbol defined.

The **Euclidean distance**, or **distance**, of two points $\mathbf{A}$ and $\mathbf{B}$ is the **length** of the vector $\mathbf{A} - \mathbf{B}$, i.e., for $\mathbf{A} = [a_1, a_2, \dots, a_n, 1]^T$ and $\mathbf{B} = [b_1, b_2, \dots, b_n, 1]^T$,

$$\|\mathbf{A} - \mathbf{B}\| = \sqrt{(a_1 - b_1)^2 + \cdots + (a_n - b_n)^2}.$$

Let $\mathcal{S} = \{\mathbf{A}_1, \mathbf{A}_2, \dots, \mathbf{A}_m\}$ be a set of points in E^n. The point

$$\mathbf{C} = a_1\mathbf{A}_1 + a_2\mathbf{A}_2 + \cdots + a_m\mathbf{A}_m \quad \text{and} \quad \sum_{k=1}^{m} a_k = 1,$$

is a **linear combination** of $\mathcal{S}$. The set of all linear combinations of $\mathcal{S}$ is the **linear hull** of $\mathcal{S}$, denoted by $\mathcal{L}(\mathcal{S})$.

A point $\mathbf{C}$ is **linearly dependent** on $\mathcal{S}$ if $\mathbf{C} \in \mathcal{L}(\mathcal{S})$. The set $\mathcal{S}$ is called **linearly dependent** if there is a point in $\mathcal{S}$ that is linearly dependent on the remaining points. Otherwise, the set $\mathcal{S}$ is called **linearly independent**.

Linear hulls of systems of points are called **linear subspaces** of E^n.

A linear subspace M has **dimension** k if the maximum number of linearly independent points in M is $k+1$.

Linear subspaces of dimension 1 in E^n are called **lines**.

Linear subspaces of dimension $n-1$ in E^n (i.e., of **codimension** 1) are called **hyperplanes**.

If $\widehat{\alpha}$ is a hyperplane in E^n defined by the equation $\alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_n x_n + \alpha_0 = 0$ (cf. Fact 10), the vector $\mathbf{u} = [\alpha_1, \ldots, \alpha_n, 0]^T$ is a **normal vector** to $\widehat{\alpha}$.

The **distance** of point $\mathbf{C}$ to a hyperplane $\widehat{\alpha}$ is the minimum of all distances of the point $\mathbf{C}$ from the points in the hyperplane $\widehat{\alpha}$.

Two hyperplanes are called **parallel** if their normal vectors are proportional, i.e., one is a scalar multiple of the other. They are called **orthogonal** (or **perpendicular**) if their normal vectors are orthogonal.

Let $\mathcal{S} = \{\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_m\}$ be a set of points in E^n. Then the set of all points of the form

$$a_1\mathbf{A}_1 + a_2\mathbf{A}_2 + \cdots + a_m\mathbf{A}_m,$$

for which all the coefficients a_i are nonnegative and $\sum a_k = 1$, is called the **convex hull** of $\mathcal{S}$; we denote it by $\mathcal{C}(\mathcal{S})$.

The convex hull of two distinct points $\mathbf{A}$, $\mathbf{B}$ is called the **segment** and is denoted by $\overline{\mathbf{AB}}$.

The point $\frac{1}{2}\mathbf{A} + \frac{1}{2}\mathbf{B}$ is the **midpoint** of the segment $\overline{\mathbf{AB}}$.

A set $\mathcal{S} \in E^n$ is **convex** if S has the property that with any two points $\mathbf{A}$ and $\mathbf{B}$ in $\mathcal{S}$, all points of the segment $\overline{\mathbf{AB}}$ are in $\mathcal{S}$.

A hyperplane $\widehat{\alpha}$ with normal vector $[\alpha_1, \alpha_2, \ldots, \alpha_n]$ determines two **open halfspaces**; one is the set of all points $\mathbf{X} = [x_1, x_2, \ldots, x_n, 1]^T$ satisfying

$$\alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_n x_n + \alpha_0 > 0,$$

while the other is the set of all points satisfying the reverse inequality.

In addition, one can speak about **closed halfspace** if in the inequality, equality is also admitted.

Facts:

These facts follow from facts in Chapter 1 and Chapter 82.

1. Points and vectors in arithmetic Euclidean n-space satisfy the following:
   (E1.) The sum of a point and a vector is a point.
   (E2.) The difference of two points is a vector.
   (E3.) $(\mathbf{C} + \mathbf{v}) + \mathbf{w} = \mathbf{C} + (\mathbf{v} + \mathbf{w})$, where $\mathbf{C}$ is a point and $\mathbf{v}$, $\mathbf{w}$ are vectors.
2. Arithmetic Euclidean n-space, with vectors acting on points by addition, is a Euclidean n-space as defined in Chapter 82.
3. A linear hull is an affine subspace as defined in Chapter 82.
4. The set $\mathcal{S} = \{\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_m\}$ is linearly independent if and only if $\lambda_1 = \lambda_2 = \cdots = \lambda_m = 0$ are the only numbers $\lambda_1, \ldots, \lambda_m$ for which the zero vector $\mathbf{0}$ satisfies $\mathbf{0} = \lambda_1\mathbf{A}_1 + \lambda_2\mathbf{A}_2 + \cdots + \lambda_m\mathbf{A}_m$ and $\sum_{k=1}^{m} \lambda_k = 0$.
5. The set $\mathcal{S} = \{\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_m\}$ is linearly independent if and only if every point $\mathbf{P} \in \mathcal{L}(\mathcal{S})$ has a unique expression as

$$\mathbf{P} = \lambda_1\mathbf{A}_1 + \lambda_2\mathbf{A}_2 + \cdots + \lambda_m\mathbf{A}_m \text{ and } \sum_{k=1}^{m} \lambda_k = 1.$$

6. A linearly independent set in E^n contains at most $n+1$ points. A linearly independent set with $n+1$ linearly independent points in E^n exists.
7. Any linearly independent set has the property that each of its nonempty subsets is linearly independent as well.
8. Let the set $\mathcal{S}$ consist of m points $\mathbf{A}$, $\mathbf{B}$, …, $\mathbf{G}$ defined by

   $$\mathbf{A} = [a_1, a_2, \ldots, a_n, 1]^T, \mathbf{B} = [b_1, b_2, \ldots, b_n, 1]^T, \ldots, \mathbf{G} = [g_1, g_2, \ldots, g_n, 1]^T.$$

   Then $\mathcal{S}$ is linearly independent if and only if the $m \times (n+1)$ matrix

   $$\begin{bmatrix} a_1 & a_2 & \ldots & a_n & 1 \\ b_1 & b_2 & \ldots & b_n & 1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ g_1 & g_2 & \ldots & g_n & 1 \end{bmatrix}$$

   has rank m.
9. Let $\mathbf{A} = [a_1, a_2, \ldots, a_n, 1]^T$, $\mathbf{B} = [b_1, b_2, \ldots, b_n, 1]^T$, …, $\mathbf{F} = [f_1, f_2, \ldots, f_n, 1]^T$ be n linearly independent points in E^n. Then the linear hull of these points consists of all points $\mathbf{X} = [x_1, x_2, \ldots, x_n, 1]^T$ in E^n which satisfy the equation

   $$\det \begin{bmatrix} x_1 & x_2 & \ldots & x_n & 1 \\ a_1 & a_2 & \ldots & a_n & 1 \\ b_1 & b_2 & \ldots & b_n & 1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ f_1 & f_2 & \ldots & f_n & 1 \end{bmatrix} = 0.$$

10. A hyperplane can be characterized as the set of points $\mathbf{X} = [x_1, x_2, \ldots, x_n, 1]^T$ such that the coordinates satisfy one linear equation of the form

    $$\alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_n x_n + \alpha_0 = 0,$$

    in which not all of the numbers $\alpha_1, \alpha_2, \ldots, \alpha_n$ are equal to zero.
11. We can generalize linear independence as well as the equation of the hyperplane in Fact 9 by including cases when some of the points (but not all of them) are replaced by vectors. We simply put into the corresponding row the $(n+1)$-tuple $a_1, a_2, \ldots, a_n, 0$ instead of that for the point.
12. Two parallel but distinct hyperplanes have no point in common. Conversely, if two hyperplanes in E^n, $n \geq 2$, have no point in common, then they are parallel.
13. Hyperplanes are parallel if and only if they are parallel as affine subspaces as defined in Chapter 82.
14. The definitions of segment and midpoint are equivalent to the definitions of these terms in Chapter 82 for arithmetic Euclidean n-space.
15. The distance of a point $\mathbf{C} = [c_1, c_2, \ldots, c_n, 1]^T$ from a hyperplane $\widehat{\alpha}$ given by equation $\alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_n x_n + \alpha_0 = 0$ is

    $$\frac{|\alpha_1 c_1 + \alpha_2 c_2 + \cdots + \alpha_n c_n + \alpha_0|}{\sqrt{\alpha_1^2 + \alpha_2^2 + \cdots + \alpha_n^2}}.$$

16. The distance of a point $\mathbf{C} = [c_1, c_2, \ldots, c_n, 1]^T$ from a hyperplane $\widehat{\alpha}$ given by equation $\alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_n x_n + \alpha_0 = 0$ is the distance of $\mathbf{C}$ from the point $\mathbf{F} = \mathbf{C} - \gamma \mathbf{u}$, where $\mathbf{u} = [\alpha_1, \alpha_2, \ldots, \alpha_n, 0]^T$ is the normal vector to $\widehat{\alpha}$ and

    $$\gamma = \frac{\alpha_1 c_1 + \alpha_2 c_2 + \cdots + \alpha_n c_n + \alpha_0}{\alpha_1^2 + \alpha_2^2 + \cdots + \alpha_n^2}.$$

Examples:

1. In E^3, the points $\mathbf{A}_1 = [2, -1, 2, 1]^T$, $\mathbf{A}_2 = [1, 1, 3, 1]^T$, and $\mathbf{A}_3 = [0, 0, 1, 1]^T$ are linearly independent since the rank of the matrix

$$\begin{bmatrix} 2 & -1 & 2 & 1 \\ 1 & 1 & 3 & 1 \\ 0 & 0 & 1 & 1 \end{bmatrix}$$

is 3.

2. The point $\mathbf{A}_4 = [2, 0, 3, 1]^T$ is linearly dependent on the points $\mathbf{A}_1, \mathbf{A}_2$, and $\mathbf{A}_3$ from Example 1, since $\mathbf{A}_4 = \frac{2}{3}\mathbf{A}_1 + \frac{2}{3}\mathbf{A}_2 - \frac{1}{3}\mathbf{A}_3$.
3. The equation of the hyperplane (which is a plane) determined by the points in Example 1 is

$$0 = \det \begin{bmatrix} x_1 & x_2 & x_3 & 1 \\ 2 & -1 & 2 & 1 \\ 1 & 1 & 3 & 1 \\ 0 & 0 & 1 & 1 \end{bmatrix} = -3x_1 - 3x_2 + 3x_3 - 3.$$

4. The triangle with vertices $\mathbf{A}_1, \mathbf{A}_2, \mathbf{A}_3$ from Example 1 is the convex hull of the three points $\mathbf{A}_1, \mathbf{A}_2$, and $\mathbf{A}_3$.
5. Let $n \geq 3$ be an integer. In the Euclidean n-space E^n, define points

$$\mathbf{F}_k = [\underbrace{n-k, n-k, \ldots, n-k}_{k-\text{times}}, \underbrace{-k, -k, \ldots, -k}_{(n-k)-\text{times}}, 1], \quad k = 1, \ldots, n;$$

$$\mathbf{F}_0 = [n-1, n-2, \ldots, 0, 1]^T, \text{and}$$

$$\mathbf{C} = \left[\frac{1}{2}(n-1), \frac{1}{2}(n-3), \frac{1}{2}(n-5), \ldots, -\frac{1}{2}(n-3), -\frac{1}{2}(n-1), 1\right]^T.$$

Observe first that the points $\mathbf{C}$, $\mathbf{F}_1$, $\mathbf{F}_2$, $\ldots$, $\mathbf{F}_n$ are linearly dependent since $\mathbf{C} = \frac{1}{n}\mathbf{F}_1 + \frac{1}{n}\mathbf{F}_2 + \cdots + \frac{1}{n}\mathbf{F}_n$.

On the other hand, the points $\mathbf{F}_0, \mathbf{F}_1, \ldots, \mathbf{F}_n$ form a linearly independent set by Fact 8 since the determinant (of an $(n+1) \times (n+1)$ matrix)

$$\det \begin{bmatrix} n-1 & n-2 & n-3 & n-4 & \ldots & 0 & 1 \\ n-1 & -1 & -1 & -1 & \ldots & -1 & 1 \\ n-2 & n-2 & -2 & -2 & \ldots & -2 & 1 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 2 & 2 & 2 & 2 & \ldots & -(n-2) & 1 \\ 1 & 1 & 1 & 1 & \ldots & -(n-1) & 1 \\ 0 & 0 & 0 & 0 & \ldots & 0 & 1 \end{bmatrix}$$

is different from zero: Subtracting the $\frac{1}{n}$-multiple of the sum of the second to last row, from the first row, the first row is a $\frac{1}{2}(n-1)$-multiple of the row of all ones. Factoring out this number $\frac{1}{2}(n-1)$ from the determinant, subtracting the resulting first row from the nth row, the 2-multiple of the first row from the $(n-1)$st row, etc., until the $(n-1)$-multiple of the first row from the second row, we obtain the determinant of an upper triangular matrix with all diagonal entries different from zero. The value of the determinant is then also easily determined.

The Euclidean distances between the points $\mathbf{F}_i$ and $\mathbf{F}_{i+1}$, $i = 1, \ldots, n-1$, as well as between $\mathbf{F}_n$ and $\mathbf{F}_i$, are all equal, equal to $\sqrt{n(n-1)}$. The point $\mathbf{C}$ has the same distances from all points $\mathbf{F}_i$, $i = 1, 2, \ldots, n$, equal to $\sqrt{\frac{1}{12}(n-1)n(n+1)}$.

All the points $\mathbf{F}_i$, $i = 1, 2, \ldots, n$, as well as the point $\mathbf{C}_i$, are points of the hyperplane H with equation $\sum_{i=1}^{n} x_i = 0$.

The vector $\mathbf{F}_0 - \mathbf{C}$ is the $\frac{1}{2}(n-1)$-multiple of the vector $\mathbf{u} = [1, 1, \ldots, 1]^T$ (which is throughout denoted as $\mathbf{1}$). This vector is at the same time the normal vector to the hyperplane H. It follows that the distance of the point $\mathbf{F}_0$ from H is equal to the length of the vector $\mathbf{F}_0 - \mathbf{C}$, which is $\frac{1}{2}(n-1)\sqrt{n}$. The same result can be obtained using Fact 15.

The hyperplane with equation

$$x_1 + x_2 + \cdots + x_n - 1 = 0$$

is parallel to H; the hyperplane

$$x_1 - x_2 = 0$$

is orthogonal to H since the vector $[1, -1, 0, \ldots, 0, 0]^T$ is orthogonal to the vector $\mathbf{u}$.

83.2 Gram Matrices

Definitions:

The **Gram matrix** $G(S)$ of an ordered system $S = (\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_m)$ of vectors in the Euclidean vector n-space $\mathbb{R}^n$ is the $m \times m$ matrix $G(S) = G(\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_m) = [\langle \mathbf{a}_i, \mathbf{a}_j \rangle]$. (See also Section 9.1.).

Let $\mathbf{O}$, $\mathbf{A}_1$, $\mathbf{A}_2$,..., $\mathbf{A}_k$, $k \geq 2$, be linearly independent points in E^n, and let $\mathbf{u}_1 = \mathbf{A}_1 - \mathbf{O}, \mathbf{u}_2 = \mathbf{A}_2 - \mathbf{O}, \ldots, \mathbf{u}_k = \mathbf{A}_k - \mathbf{O}$, be the corresponding vectors. We call the set of all points of the form $\mathbf{O} + \sum_{i=1}^{k} a_k \mathbf{u}_k$, where the numbers a_i satisfy $0 \leq a_i \leq 1$, $i = 1, \ldots, k$, the **parallelepiped** spanned by the vectors $\mathbf{u}_i$. For $k = 2$, we speak about the **parallelogram** spanned by $\mathbf{u}_1$ and $\mathbf{u}_2$.

If $\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n$ is a basis of an n-dimensional arithmetic Euclidean vector space and $\mathbf{v}_1, \mathbf{v}_2, \ldots,$ $\mathbf{v}_n$ is a set of vectors such that the inner product of $\mathbf{u}_i$ and $\mathbf{v}_j$ is the Kronecker delta δ_{ij}, then this pair of ordered sets is a **biorthogonal pair of bases**.

Facts:

Facts for which no specific reference is given follow from facts in Chapter 1.

1. The Gram matrix is always a positive semidefinite matrix. Its rank is equal to the dimension of the Euclidean space of smallest dimension which contains all the vectors of the system.
2. Every positive semidefinite matrix is a Gram matrix of some system of vectors S in some Euclidean space.
3. Every linear relationship among the vectors in S is reflected in the same linear relationship among the rows of $G(S)$, and conversely.
4. The k-dimensional volume of the parallelepiped spanned by the vectors $\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_k$ is
$$\sqrt{\det G(\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_k)}.$$
5. To every basis $\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n$ of an n-dimensional Euclidean vector space there exists a set of vectors $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$ such that this pair is a biorthogonal pair of bases. The set of the $\mathbf{v}_i$s is also a basis and is uniquely determined.
6. If both bases in the biorthogonal pair coincide, the common basis is orthonormal, and an orthonormal basis forms a biorthogonal pair with itself.
7. The Gram matrices $G(\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n)$ and $G(\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n)$ of a pair of biorthogonal bases are inverse to each other:
$$G(\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n)G(\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n) = I.$$

8. [Fie64] Let $A = [a_{ij}]$ be a positive semidefinite matrix with row sums zero. Then
$$2 \max_i \sqrt{a_{ii}} \leq \sum_i \sqrt{a_{ii}}.$$
9. [Fie61c] If A is positive definite, then the matrix $A \circ A^{-1} - I$ is positive semidefinite and its row sums are equal to zero.
10. If $A = [a_{ij}]$ is positive definite and $A^{-1} = [\alpha_{ij}]$, then
$$a_{ii}\alpha_{ii} \geq 1 \quad \text{for all } \ i$$
and
$$2 \max_i \sqrt{a_{ii}\alpha_{ii} - 1} \leq \sum_i \sqrt{a_{ii}\alpha_{ii} - 1}.$$
11. [Fie64] Let $A = [a_{ik}]$ be a positive definite matrix, and let $A^{-1} = [\alpha_{ik}]$. Then the diagonal entries of A and A^{-1} satisfy the first condition in Fact 10 and
$$2 \max_i (\sqrt{a_{ii}\alpha_{ii}} - 1) \leq \sum_i (\sqrt{a_{ii}\alpha_{ii}} - 1).$$
Conversely, if some n-tuples of positive numbers a_{ii} and α_{ii} satisfy these conditions, then there exists a positive definite $n \times n$ matrix A with diagonal entries a_{ii} such that the diagonal entries of A^{-1} are α_{ii}.
12. [Fie64] Let the vectors $\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_n$, $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$ form a pair of biorthogonal bases in a Euclidean n-space E. Then
$$\|\mathbf{u}_i\|\|\mathbf{v}_i\| \geq 1, \quad i = 1, \ldots, n,$$
$$2 \max_i (\|\mathbf{u}_i\|\|\mathbf{v}_i\| - 1) \leq \sum_i (\|\mathbf{u}_i\|\|\mathbf{v}_i\| - 1).$$
Conversely, if nonnegative numbers $\alpha_1, \alpha_2, \ldots, \alpha_n$, $\beta_1, \beta_2, \ldots, \beta_n$ satisfy
$$\alpha_i\beta_i \geq 1, \quad i = 1, \ldots, n,$$
$$2 \max_i (\alpha_i\beta_i - 1) \leq \sum_i (\alpha_i\beta_i - 1),$$
then there exists in E^n a pair of biorthogonal bases $\mathbf{u}_i$, $\mathbf{v}_j$, such that
$$\|\mathbf{u}_i\| = \alpha_i, \|\mathbf{v}_i\| = \beta_i, \quad i = 1, \ldots, n.$$
13. [Fie64] Let $A = [a_{ij}]$ be an $n \times n$ positive definite matrix, $n \geq 2$, and let $A^{-1} = [\alpha_{ij}]$. Then the following are equivalent:
    (a) $\sqrt{a_{nn}\alpha_{nn}} - 1 = \sum_{i=1}^{n-1} (\sqrt{a_{ii}\alpha_{ii}} - 1)$.
    (b) $\frac{a_{ij}}{\sqrt{a_{ii}}\sqrt{a_{jj}}} = \frac{\alpha_{ij}}{\sqrt{\alpha_{ii}}\sqrt{\alpha_{jj}}}$, $i, j = 1, \ldots, n-1$, and
    $\frac{a_{in}}{\sqrt{a_{ii}}\sqrt{a_{nn}}} = -\frac{\alpha_{in}}{\sqrt{\alpha_{ii}}\sqrt{\alpha_{nn}}}$, $i = 1, \ldots, n-1$.
    (c) A is diagonally similar to
    $$C = \begin{bmatrix} I_1 + \omega \mathbf{c}\mathbf{c}^T & \mathbf{c} \\ \mathbf{c}^T & 1 + \omega \mathbf{c}^T\mathbf{c} \end{bmatrix},$$
    where $\mathbf{c}$ is a real vector with $n-1$ coordinates and
    $$\omega = \frac{\sqrt{1 + \mathbf{c}^T\mathbf{c}} - 1}{\mathbf{c}^T\mathbf{c}}$$
    if $\mathbf{c} \neq \mathbf{0}$; if $\mathbf{c} = \mathbf{0}$, $\omega = 0$.

14. To realize a positive definite $n \times n$ matrix C as a Gram matrix of some n vectors, say $\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_n$, it suffices to find a nonsingular matrix A such that $C = AA^T$ and to use the entries in the kth row of A as coordinates of the vector $\mathbf{a}_k$. Such matrix A can be found, e.g., by the Gram–Schmidt process (cf. Section 5.5).

Examples:

1. The vectors $\mathbf{u}_1 = [1, 3]^T$, $\mathbf{u}_2 = [2, -1]^T$ in $\mathbb{R}^2$ are linearly independent and form a basis in $\mathbb{R}^2$. The Gram matrix $G(\mathbf{u}_1, \mathbf{u}_2) = \begin{bmatrix} 10 & -1 \\ -1 & 5 \end{bmatrix}$ is nonsingular.
2. To find the pair of vectors $\mathbf{v}_1, \mathbf{v}_2$ that form a biorthogonal pair with the vectors $\mathbf{u}_1, \mathbf{u}_2$ in Example 1, observe that $\mathbf{v}_1$ should satisfy $\langle \mathbf{u}_1, \mathbf{v}_1 \rangle = 1$ and $\langle \mathbf{u}_2, \mathbf{v}_1 \rangle = 0$. Set $\mathbf{v}_1 = [x_1, x_2]^T$; thus, $x_1 + 3x_2 = 1$, $2x_1 - x_2 = 0$, i.e., $\mathbf{v}_1 = [\frac{1}{7}, \frac{2}{7}]^T$. Analogously, $\mathbf{v}_2 = [\frac{3}{7}, -\frac{1}{7}]^T$. The Gram matrix is $G(\mathbf{v}_1, \mathbf{v}_2) = \begin{bmatrix} \frac{5}{49} & \frac{1}{49} \\ \frac{1}{49} & \frac{10}{49} \end{bmatrix}$. It is easily verified that $G(\mathbf{v}_1, \mathbf{v}_2)$ is the inverse of $G(\mathbf{u}_1, \mathbf{u}_2)$, as stated in Fact 7.
3. The pairs of vectors ($\mathbf{e}_1 = [1, 0]^T$, $\mathbf{e}_2 = [0, 1]^T$) and ($\mathbf{u}_1 = [\frac{3}{5}, \frac{4}{5}]^T$, $\mathbf{u}_2 = [\frac{-4}{5}, \frac{3}{5}]^T$) are orthonormal bases for $\mathbb{R}^2$, so $G(\mathbf{e}_1, \mathbf{e}_2) = I$ and $G(\mathbf{u}_1, \mathbf{u}_2) = I$ are inverses, but $(\mathbf{e}_1, \mathbf{e}_2)$ and $(\mathbf{u}_1, \mathbf{u}_2)$ are not a biorthogonal pair of bases.

83.3 General Theory of Euclidean Simplexes

An n-simplex in E^n is a generalization of the triangle in the plane and the tetrahedron in the three-dimensional space. Just as not every triplet of positive numbers can serve as lengths of three sides of a triangle (they have to satisfy the strict triangle inequality), we can ask about analogous conditions for the simplex.

Definitions:

An **n-simplex** is the convex hull of $n + 1$ linearly independent points in E^n.

The points are called **vertices** of the simplex. The convex hull of a subset of the set of vertices is called a **face** of the simplex.

If the subset of vertices has $k + 1$ elements, the face has **dimension** k. One-dimensional faces are called **edges**.

If $\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_{n+1}$ are the vertices of an n-simplex Σ, we write $\Sigma = \{\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_{n+1}\}$. The $(n - 1)$-dimensional face opposite $\mathbf{A}_i$ is denoted by ω_i. A vector $\mathbf{n}$ is an **outer normal** to ω_i if $\mathbf{n}$ is a normal to ω_i and for $\mathbf{C} \in \omega_i$, $\mathbf{C} + \mathbf{n}$ is not in the same halfspace as $\mathbf{A}_i$.

The **dihedral interior angle** between ω_i and ω_j, $i \neq j$ (opposite the edge $\mathbf{A}_i\mathbf{A}_j$) is $\pi-$(the angle between an outer normal to ω_i and an outer normal to ω_j), and is denoted by ϕ_{ij}.

The **barycentric coordinates** with respect to the simplex $\Sigma = \{\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_{n+1}\}$ of a point $\mathbf{P}$ in $\mathcal{L}(\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_{n+1})$ are the unique numbers λ_i such that $\mathbf{P} = \lambda_1\mathbf{A}_1 + \lambda_2\mathbf{A}_2 + \cdots + \lambda_{n+1}\mathbf{A}_{n+1}$ and $\sum_{k=1}^{n+1} \lambda_k = 1$ (cf. Fact 83.1.5). Strictly speaking, these numbers are the **inhomogeneous barycentric coordinates**.

The **homogeneous barycentric coordinates** of $\lambda_1\mathbf{A}_1 + \lambda_2\mathbf{A}_2 + \cdots + \lambda_{n+1}\mathbf{A}_{n+1}$ are the numbers λ_i (not all 0). The expression $\lambda_1\mathbf{A}_1 + \lambda_2\mathbf{A}_2 + \cdots + \lambda_{n+1}\mathbf{A}_{n+1}$ means a **proper point** if $\sum_{k=1}^{n+1} \lambda_k \neq 0$ (namely the point with inhomogeneous barycentric coordinates $\rho\lambda_1, \ldots, \rho\lambda_{n+1}$ with $\rho = (\sum_{k=1}^{n+1} \lambda_k)^{-1}$), or an **improper point** (determined by the (nonzero) vector $\lambda_1\mathbf{A}_1 + \lambda_2\mathbf{A}_2 + \cdots + \lambda_{n+1}\mathbf{A}_{n+1}$) if $\sum_{k=1}^{n+1} \lambda_k = 0$. These coordinates can be viewed as in projective n-dimensional geometry (see Chapter 82). The set of improper points is, thus, characterized by the equation $\sum_{k=1}^{n+1} \lambda_k = 0$ in homogeneous barycentric coordinates, and is called the **improper hyperplane**.

The **circumcenter** of a simplex is the point that is equidistant from all the vertices of the simplex. The set of all points at that common distance from the circumcenter is the **circumscribed hypersphere**.

The $(n+1)\times(n+1)$ matrix $M=[m_{ij}]$ with m_{ij} equal to the square of the distance between the ith and jth vertex of an n-simplex Σ is called the **Menger matrix** of Σ.

The **Gramian** of an n-simplex $\Sigma=\{\mathbf{A}_1,\mathbf{A}_2,\dots,\mathbf{A}_{n+1}\}$ is defined as the Gram matrix Q of $n+1$ vectors $\mathbf{n}_1,\mathbf{n}_2,\dots,\mathbf{n}_{n+1}$ determined as follows: The first n of them form the biorthogonal pair with the n vectors $\mathbf{u}_1=\mathbf{A}_1-\mathbf{A}_{n+1},\mathbf{u}_2=\mathbf{A}_2-\mathbf{A}_{n+1},\dots,\mathbf{u}_n=\mathbf{A}_n-\mathbf{A}_{n+1}$, the remaining $\mathbf{n}_{n+1}$ is defined by $\mathbf{n}_{n+1}=-\sum_{i=1}^{n}\mathbf{n}_i$.

Facts:

1. There are $\binom{n+1}{2}$ edges $\{\mathbf{A}_i,\mathbf{A}_j\}$, $i\neq j$, in an n-simplex.
2. A 2-simplex is a segment and its circumcenter is its midpoint. The circumcenter of an n-simplex is the intersection of the lines ℓ_i, where ℓ_i is the line normal to face ω_i and through the circumcenter of ω_i.
3. [Blu53] (Menger, Schoenberg, etc.) The numbers m_{ij}, $i,j=1,\dots,n+1$, can serve as squares of the lengths of edges (i.e., of distances between vertices) of an n-simplex if and only if $m_{ii}=0$ for all i, and
$$\sum_{i,j} m_{ij}x_ix_j<0,\quad\text{whenever}\quad \sum_i x_i=0.$$
4. (Consequence of Fact 3) The matrix
$$M_0=\begin{bmatrix}0 & \mathbf{1}^T\\ \mathbf{1} & M\end{bmatrix},$$
where $\mathbf{1}$ is the column vector of all ones and $M=[m_{ij}]$ is a Menger matrix, is elliptic, i.e., has one eigenvalue positive and the remaining negative.
5. The Menger matrix is the matrix of the quadratic form $\sum_{i,j} m_{ij}x_ix_j$. If $x_1,\dots,x_{n+1}$ are considered as homogeneous barycentric coordinates of the point $\mathbf{X}=[x_1,\dots,x_{n+1}]$, then the equation
$$\sum_{i,j} m_{ij}x_ix_j=0$$
is the equation of the circumscribed hypersphere of the n-simplex Σ. (Thus, the condition in Fact 3 can be interpreted that for all improper points, the value of the quadratic form $\sum_{i,j} m_{ij}x_ix_j$ is strictly negative.)
6. The n-dimensional volume V of an n-simplex Σ satisfies
$$V^2=\frac{(-1)^{n-1}}{2^n(n!)^2}\det M_0,$$
where M_0 is the matrix in Fact 4 using the Menger matrix M of Σ.
7. The volume V_s of the n-simplex with vertices in $\mathbf{O},\mathbf{A}_1,\dots,\mathbf{A}_n$ is equal to $V_s=\frac{1}{n!}V_p$, where V_p is the volume of the parallelepiped defined in Fact 83.2.4 by n vectors $\mathbf{A}_i-\mathbf{O}$. Thus, $V_s=\frac{1}{n!}\sqrt{\det G(\mathbf{u}_1,\dots,\mathbf{u}_n)}$, where $G(\dots)$ means the Gram matrix and $\mathbf{u}_k=\mathbf{A}_k-\mathbf{O}$.
8. Let $Q_0=\begin{bmatrix}q_{00} & \mathbf{q}_0^T\\ \mathbf{q}_0 & Q\end{bmatrix}$, where the matrix Q is the Gramian of the n-simplex Σ, the numbers in the column vector $\mathbf{q}_0$ are (-2)-multiples of the inhomogeneous barycentric coordinates of the circumcenter of Σ, and $\frac{1}{2}\sqrt{q_{00}}$ is the radius of the circumsphere of Σ. Then $M_0Q_0=-2I$.

9. The vectors $\mathbf{n}_1, \mathbf{n}_2, \ldots, \mathbf{n}_{n+1}$ from the definition of the Gramian are the vectors of outer normals of the simplex, in some sense normalized.
10. The Gramian of every n-simplex is an $(n+1) \times (n+1)$ positive semidefinite matrix of rank n with row sums equal to zero. Conversely, every such matrix determines uniquely (apart from the position in the space) an n-simplex in E^n whose Gramian this matrix is.
11. Let Σ_S be a face of an n-simplex Σ determined by the vertices with index set $S \subset \{1, \ldots, n+1\}$. Let Q be the Gramian of Σ. Then the Gramian of Σ_S is the Schur complement $Q/Q(S)$, where $Q(S)$ denotes the principal submatrix of Q corresponding to indices in the complement of S.

Examples:

1. Let us find the Menger matrix and the Gramian in the case of the segment $\{\mathbf{A}_1, \mathbf{A}_2\}$ of length d (i.e., a 1-simplex). The Menger matrix is $\begin{bmatrix} 0 & d^2 \\ d^2 & 0 \end{bmatrix}$. If $\mathbf{u}_1 = \mathbf{A}_1 - \mathbf{A}_2$, then $\mathbf{n}_1 = \frac{1}{d^2}\mathbf{u}_1$ since $\langle \mathbf{u}_1, \mathbf{n}_1 \rangle$ has to be 1. Thus, the Gramian is the Gram matrix $G(\mathbf{n}_1, -\mathbf{n}_1)$, i.e., $\begin{bmatrix} \frac{1}{d^2} & -\frac{1}{d^2} \\ -\frac{1}{d^2} & \frac{1}{d^2} \end{bmatrix}$.

   Indeed, $\begin{bmatrix} 0 & 1 & 1 \\ 1 & 0 & d^2 \\ 1 & d^2 & 0 \end{bmatrix} \begin{bmatrix} d^2 & -1 & -1 \\ -1 & \frac{1}{d^2} & -\frac{1}{d^2} \\ -1 & -\frac{1}{d^2} & \frac{1}{d^2} \end{bmatrix} = -2I_3$, as asserted in Fact 8.
2. Consider the simplex $\Sigma = \{\mathbf{A}_1 = [0,0,1]^T,\ \mathbf{A}_2 = [1,0,1]^T,\ \mathbf{A}_3 = [1,2,1]^T\}$ in E^2. We show how Fact 6 and Fact 7 can be used to find the volume V of this simplex.

   To use Fact 6, compute the squares of the distances between the vertices to obtain the Menger matrix: $M = \begin{bmatrix} 0 & 1 & 5 \\ 1 & 0 & 4 \\ 5 & 4 & 0 \end{bmatrix}$, so $M_0 = \begin{bmatrix} 0 & 1 & 1 & 1 \\ 1 & 0 & 1 & 5 \\ 1 & 1 & 0 & 4 \\ 1 & 5 & 4 & 0 \end{bmatrix}$. Since $\det M_0 = -16$, $V = 1$ by Fact 6.

   To use Fact 7, compute the vectors $\mathbf{u}_1 = [1,0,0]^T$ and $\mathbf{u}_2 = [1,2,0]^T$, so $G(\mathbf{u}_1, \mathbf{u}_2) = \begin{bmatrix} 1 & 1 \\ 1 & 5 \end{bmatrix}$. By Fact 7, $V = \frac{1}{2!}\sqrt{\det G(\mathbf{u}_1, \mathbf{u}_2)} = \frac{1}{2}\sqrt{4} = 1$.

   In this example, the volume can be found directly by finding the area of the triangle.
3. Consider the simplex in Example 2. Let us compute the Gramian to illustrate Fact 8 for this simplex. Since $\mathbf{u}_1 = \mathbf{A}_1 - \mathbf{A}_3 = [-1,-2,0]^T$, $\mathbf{u}_2 = \mathbf{A}_2 - \mathbf{A}_3 = [0,-2,0]^T$, the vectors $\mathbf{n}_1, \mathbf{n}_2$ forming a biorthogonal pair with $\mathbf{u}_1, \mathbf{u}_2$ are (as in Example 83.2.2) $\mathbf{n}_1 = [-1,0,0]^T$, $\mathbf{n}_2 = [1, -\frac{1}{2}, 0]^T$. Thus, $\mathbf{n}_3 = [0, \frac{1}{2}, 0]^T$ and $G(\mathbf{n}_1, \mathbf{n}_2, \mathbf{n}_3) = \begin{bmatrix} 1 & -1 & 0 \\ -1 & \frac{5}{4} & -\frac{1}{4} \\ 0 & -\frac{1}{4} & \frac{1}{4} \end{bmatrix}$. The line ℓ_1 is the set of points of the form $[x,1,1]^T$, and line ℓ_3 is the set of points of the form $[\frac{1}{2}, y, 1]^T$, so the circumcenter of the simplex is $\mathbf{c} = [\frac{1}{2}, 1, 1]^T$. The (inhomogeneous) barycentric coordinates b_1, b_2, b_3 of $\mathbf{c}$ can be found by solving $b_1\mathbf{A}_1 + b_2\mathbf{A}_2 + b_3\mathbf{A}_3 = \mathbf{c}$, $b_1 + b_2 + b_3 = 1$ to obtain $b_1 = \frac{1}{2}, b_2 = 0, b_3 = \frac{1}{2}$. The radius of the circumsphere is $\frac{\sqrt{5}}{2}$, so $q_{00} = 5$. Thus,

   $$Q_0 = \begin{bmatrix} 5 & -1 & 0 & -1 \\ -1 & 1 & -1 & 0 \\ 0 & -1 & \frac{5}{4} & -\frac{1}{4} \\ -1 & 0 & -\frac{1}{4} & \frac{1}{4} \end{bmatrix},$$ which is indeed equal to the matrix $-2M_0^{-1}$.

83.4 Special Simplexes

Definitions:

Let us color an edge $\{\mathbf{A}_i, \mathbf{A}_j\}$ of an n-simplex with vertices $\mathbf{A}_1, \dots, \mathbf{A}_{n+1}$, $n \geq 2$, in **red**, if the opposite interior angle ϕ_{ij} is acute; **blue**, if the opposite interior angle ϕ_{ij} is obtuse; it will stay **uncolored**, if the opposite interior angle ϕ_{ij} is right.

The edge $\{\mathbf{A}_i, \mathbf{A}_k\}$ is called **colored** if it is colored red or blue. The assignment of red and blue colors is a **coloring** of the simplex.

The **graph** of the n-simplex is the graph with vertices $1, 2, \dots, n+1$ and edges $\{i, k\}$, $i \neq k$, for which $\{\mathbf{A}_i, \mathbf{A}_k\}$ is colored. The **colored graph** of the simplex is the graph of the simplex colored in red and blue in the same way as the corresponding edges of the simplex.

An n-simplex is called **hyperacute** if each of its dihedral interior angles ϕ_{ij} is either acute or right.

A hyperacute n-simplex is called **totally hyperacute** if its circumcenter is either an interior point of the simplex, or an interior point of one of its faces.

Let $\mathbf{C}$ denote the circumcenter of the n-simplex with vertices $\mathbf{A}_1, \dots, \mathbf{A}_{n+1}$. We extend the coloring of the simplex as follows: We assign the segment $\overline{\mathbf{CA}_k}$ the **red** color if the point $\mathbf{C}$ is in the same open halfspace determined by the face ω_k as the vertex $\mathbf{A}_k$, and the **blue** color if $\mathbf{C}$ is in the opposite open halfspace. We do not assign to $\overline{\mathbf{CA}_k}$ any color if $\mathbf{C}$ belongs to ω_k. This is the **extended coloring** of the simplex.

In the same way, we speak about the **extended graph** and **extended colored graph** of the simplex, adding to $n+1$ vertices another vertex $n+2$ which corresponds to the circumcenter.

A **right simplex** (cf. [Fie57]) is an n-simplex which has exactly n acute interior angles and all the remaining $\binom{n}{2}$ interior angles right.

In a right simplex, the edges opposite the acute angles are called **legs**. The subgraph of legs and their endpoints is called **tree of legs** (see Fact 5).

A right simplex whose tree of legs is a path is called a **Schlaefli simplex**.

The face of a right simplex spanned by all pendent vertices (i.e., vertices of degree one) of the tree of legs is called the **hypotenuse** of the simplex.

A **net** on a simplex is a subset of the set of edges (not necessarily connected) such that every vertex of the simplex belongs to some edge in the net. A net is **metric** if for each edge in the net its length is given.

A **box** in a Euclidean n-space is a parallelepiped all of whose edges at some vertex (and then at all vertices) are mutually perpendicular.

Facts (cf. [Fie57]):

1. A simplex is hyperacute if and only if it has no blue edge in its coloring.
2. The set of red edges connects all the vertices of the simplex.
3. If we color the edges of an n-simplex by the two colors red and blue in such a way that the red edges connect all vertices, then there exists such deformation of the simplex that opposite red edges there are acute, opposite blue edges are obtuse, and opposite uncolored edges are right interior angles.
4. Every n-simplex has at least n acute interior angles.
5. There exist right n-simplexes. The red edges span a tree containing all the vertices of the simplex.
6. The legs of a right simplex are mutually perpendicular.
7. The tree of legs of a right n-simplex can be completed to a (n-dimensional) box; its center of symmetry is thus the circumcenter of the simplex. Conversely, every right n-simplex can be obtained by choosing among the edges of some box a subset of n edges with the property that any two are perpendicular and together form a connected set.

These are then the legs of the simplex.

8. Let $G_T = (N, E, W)$ be a tree with the numbered vertex set $N = \{1, 2, \ldots, n+1\}$ and edge set E; let every edge $\{i, j\} \in E$ be assigned a positive number w_{ij}. Construct the matrices $Q_0 = [q_{rs}]$, $r, s = 0, 1, \ldots, n+1$, and $M = [m_{ij}]$, $i, j = 1, \ldots, n+1$, as follows:
$$q_{00} = \sum_{i,j \in E} \frac{1}{w_{ij}}, \quad q_{0i} = q_{i0} = d_i - 2, \quad i \in N,$$
where d_i is the degree of the vertex i in G_T,
$$q_{ij} = -w_{ij} \text{ if } \{i, j\} \in E, \quad q_{ii} = \sum_{j,(i,j) \in E} w_{ij}, \quad q_{ij} = 0 \text{ otherwise;}$$
$$m_{ii} = 0, \quad i \in N, \quad m_{ij} = w_{ik_1}^{-1} + w_{k_1k_2}^{-1} + \cdots + w_{k_rj}^{-1},$$
where $i, j \in N$, $i \neq j$, and $i, k_1, k_2, \ldots, k_r, j$ is the (unique) path in G_T from i to j. Then the matrices Q_0 and $M_0 = \begin{bmatrix} 0 & \mathbf{1}^T \\ \mathbf{1} & M \end{bmatrix}$ satisfy
$$M_0 Q_0 = -2I_{n+2}$$
and they are matrices corresponding to a right n-simplex whose tree of legs is G_T.
9. The inhomogeneous barycentric coordinates of the circumcenter of a right n-simplex are $q_{0i} = 1 - \frac{1}{2}d_i$, where d_i is the degree of the vertex i in the tree of legs.
10. The hypotenuse of a Schlaefli simplex is the longest edge; the midpoint of the hypotenuse is the circumcenter of the simplex.
11. Every face of a Schlaefli simplex is also a Schlaefli simplex.
12. The Schlaefli simplex is the only simplex all 2-dimensional faces of which are right triangles.
13. An n-simplex Σ is a Schlaefli simplex if and only if there exist real distinct numbers $c_1, \ldots, c_{n+1}$ such that the Menger matrix $M = [m_{ij}]$ of Σ has the form $m_{ij} = |c_i - c_j|$. If this holds for $c_1 > c_2 > \cdots > c_{n+1}$, then, in the usual notation, the edges $\{\mathbf{A}_k, \mathbf{A}_{k+1}\}$, $k = 1, \ldots, n$, are the legs of Σ.
14. Let Σ be a hyperacute n-simplex. Then the Gramian Q of Σ is a singular M-matrix of rank n, with annihilating vector $\mathbf{1}$.
15. Every face of a hyperacute simplex Σ is also a hyperacute simplex. The distribution of acute and right angles in the face is completely determined by the distribution of acute and right angles in the simplex as follows: If the face is determined by vertices with indices in S, the edge $\{\mathbf{A}_i, \mathbf{A}_j\}$ in the face will be red if and only if one can proceed from the vertex $\mathbf{A}_i$ to the vertex $\mathbf{A}_j$ along a path in the set of red edges of Σ which does not contain any vertex with index in S (except $\mathbf{A}_i$ and $\mathbf{A}_j$).
16. [Fie61a] In the extended colored graph of an n-simplex, $n \geq 2$, the red part has vertex connectivity at least two.
17. [Fie61a] In the definition of the extended graph and extended coloring, the vertex $n+2$ has no privileged position in the following sense: Let G be the extended colored graph of some n-simplex Σ_1, with vertex $n+2$ corresponding to the circumcenter of Σ_1. If $k \in \{1, 2, \ldots, n+1\}$, then there exists another n-simplex Σ_2 whose extended colored graph is G and such that k is the vertex corresponding to the circumcenter of Σ_2.
18. Every face (of dimension at least two) of a totally hyperacute simplex is also a totally hyperacute simplex. The extended coloring of the face is by the extended coloring of the simplex uniquely determined; it is obtained in the same way as in the usual coloring of a hyperacute simplex in Fact 15.

19. Let Σ be a totally hyperacute n-simplex. Then the extended graph of Σ is either a cycle, and then Σ is a Schlaefli simplex, or it has vertex connectivity at least three.
20. [Fie61a] Let a metric net N on a simplex be given. There exists a simplex of maximum volume with this net if and only if the net N is connected, i.e., if it is possible to pass from any vertex of the net to any other vertex using edges in the net only. In addition, every simplex with this maximum volume has the property that every interior angle opposite an unspecified edge of the simplex (i.e., not belonging to N) is right.

Examples:

1. Figure 83.1 shows examples of three colored triangles. In these diagrams, the heaviest line represents red, the ordinary line represents blue, and the light gray line represents white.

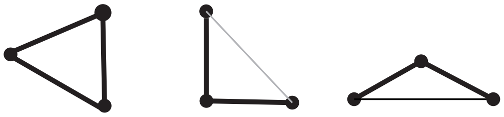

FIGURE 83.1 Coloring of triangles.

2. Figure 83.2 shows examples of the two types of right tetrahedra. The dashed lines indicate the box described in Fact 7. The tetrahedron on the right is a Schlaefli simplex.

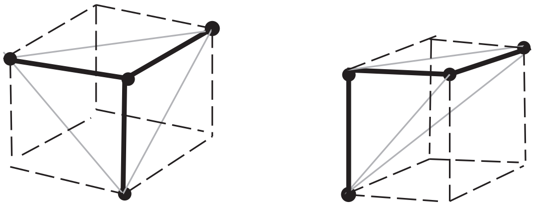

FIGURE 83.2 The two types of right tetrahedra.

3. Figure 83.3 shows examples of extended graphs of triangles in Figure 83.1.

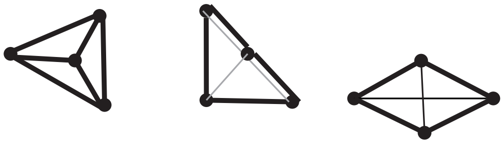

FIGURE 83.3 Extended graphs of triangles.

4. We apply the result in Fact 20 to so-called *cyclic simplexes* (cf.[Fie61a]), which are maximum volume simplexes in the case that the metric net is a cycle. We call a simplex *regularly cyclic* if all edges in this net have the same length. The Gramian of the regularly cyclic n-simplex is a multiple of the matrix

$$\begin{bmatrix} 2 & -1 & 0 & \cdots & 0 & -1 \\ -1 & 2 & -1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 2 & -1 \\ -1 & 0 & 0 & \cdots & -1 & 2 \end{bmatrix}$$

with $n+1$ rows and columns, if the net is formed by the edges $\{\mathbf{A}_k, \mathbf{A}_{k+1}\}$, $k = 1, \ldots, n$, and $\{\mathbf{A}_{n+1}, \mathbf{A}_1\}$.

The corresponding Menger matrix is then proportional to the matrix with entries $m_{ik} = |i-k|(n+1-|i-k|)$. It is possible to show that any two of the edges in the cycle span the same angle.

It is immediate that the regularly cyclic 2-simplex is the equilateral triangle. The regularly cyclic 3-simplex is the tetrahedron, which is obtained from a square by parallelly lifting one diagonal in the perpendicular direction to the plane so that the distance of the two new diagonals equals half of the length of each diagonal.

Thus, the volume of every n-simplex with vertices $\mathbf{A}_1, \mathbf{A}_2, \ldots, \mathbf{A}_{n+1}$ in a Euclidean n-space for which all the edges $\{\mathbf{A}_1, \mathbf{A}_2\}$, $\{\mathbf{A}_2, \mathbf{A}_3\}$, …, $\{\mathbf{A}_n, \mathbf{A}_{n+1}\}$, $\{\mathbf{A}_{n+1}, \mathbf{A}_1\}$ have length one, does not exceed $\frac{1}{n!}\sqrt{\frac{(n+1)^{n-1}}{n^n}}$.

83.5 An Application to Resistive Electrical Networks

We conclude with applications of matrices and graphs in another, maybe surprising, field.

Definitions:

A **resistive electrical network** is a network consisting of a finite number of nodes, say $1, 2, \ldots, n$, some pairs of which are directly connected by a conductor of some resistance. The assumptions are that the whole network is connected, and that there are no other electrical elements than resistors. As usual, **conductivity** of the conductor between two nodes is the reciprocal of the resistance of that conductor. If there is no direct connection between a pair of nodes, we set the conductivity of that "conductor" as zero.

A resistive electrical network of which just some of the nodes (**outlets**) are accessible, is called a **black-box**. The matrix of mutual resistances between the outlets of a black-box is called a **black-box matrix**.

The **problem** is: Characterize the set of all possible black-box $n \times n$ matrices.

Facts [Moo68], [Fie78]

1. Resistances of conductors in series add and conductivities of conductors in parallel add. If conductors having resistances R_1, R_2 are placed in series (see left illustration in Figure 83.4) the resistance R between the nodes is $R_1 + R_2$. If conductors having resistances R_1, R_2 are placed in parallel (see right illustration in Figure 83.4) the resistance R between the nodes satisfies $\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2}$.

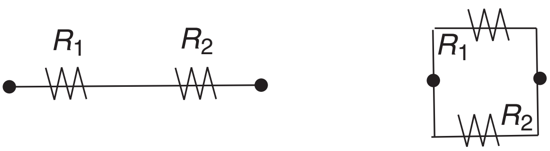

FIGURE 83.4 Resistors in series and parallel.

2. The 3×3 black-box matrices are all matrices

$$\begin{bmatrix} 0 & r_{12} & r_{13} \\ r_{12} & 0 & r_{23} \\ r_{13} & r_{23} & 0 \end{bmatrix}$$

in which the numbers r_{12}, r_{13}, and r_{23} are nonnegative, at least two different from zero, and fulfill the nonstrict triangle inequality.

3. The $n \times n$ black-box matrices are exactly Menger matrices of hyperacute $(n-1)$-simplexes.
4. If a black-box matrix is given, then the corresponding network can be realized as such for which the conductivities between pairs of outlets are equal to the negatively taken corresponding entries of the Gramian of the simplex whose Menger matrix the given matrix is.
5. [Fie78] Let the given black-box B with n outlets correspond to an $(n-1)$-simplex Σ. Let S be a nonvoid proper subset of the set of outlets of B. Join all outlets in S by shortcuts. The resulting device can be considered as a new black-box B_S, which has just one outlet instead of those outlets in S and, of course, all the remaining outlets. We construct the simplex corresponding to B_S and its black-box matrix as follows.

   If L is the linear space in the corresponding E^{n-1} determined by the vertices corresponding to S, project orthogonally all the remaining vertices as well as L itself on (some) orthogonal complement $L^{\perp}$ to L, thus obtaining a new simplex. The Menger matrix M_S of this simplex will be the black-box matrix of B_S. An algebraic construction is to pass from the Menger matrix of Σ, to the Gramian Q of Σ using Fact 83.3.8; in this Gramian Q, add together all the rows corresponding to S into a single row and all the columns corresponding to S into a single column. The resulting symmetric matrix $\hat{Q}$ is again a singular M-matrix with row-sums zero. The simplex whose Gramian is $\hat{Q}$ is then that whose Menger matrix is B_S.
6. Let S_1 and S_2 be two disjoint nonempty subsets of the set of outlets of a black-box, and let Σ be the simplex in the geometric model. Join all outlets in S_1 with a source of potential zero, and all outlets in S_2 with the source of potential one. What will be the distribution of potentials in the remaining outlets using the geometric interpretation?

   The answer is: Let L_1, L_2, respectively, be linear spaces determined by vertices of Σ corresponding to S_1, S_2, respectively. There exists a unique pair of parallel hyperplanes H_1 and H_2, such that H_1 contains L_1 and H_2 contains L_2, and the distance between H_1 and H_2 is maximal among all such pairs of parallel hyperplanes. Then the square of the distance of the hyperplanes H_1 and H_2 measures the resistance between S_1 and S_2 (similarly like the square of the distance between two vertices of Σ measures the resistance between the corresponding outlets), and if V_0 is a vertex corresponding to an outlet S_0, then the potential in S_0 is obtained by linear interpolation corresponding to the position of the hyperplane H_0 containing V_0 and parallel to H_1 with respect to the hyperplanes H_1 and H_2. Let us remark that the whole simplex Σ is in the layer between H_1 and H_2, thanks to the property of hyperacuteness of Σ.

Examples:

1. Suppose the three nodes 1, 2, and 3 are connected as follows: The nodes 1 and 2 are connected by a conductor of resistance 18 ohms, the nodes 1 and 3 by a conductor of resistance 12 ohms, and the nodes 2 and 3 by a conductor of resistance 6 ohms. We compute the resistances for the black-box with the three outlets 1, 2, and 3. For r_{12}, the total resistance between outlets 1 and 2, note that there are two parallel paths between 1 and 2: the direct path with resistance 18 ohms, and the path through node 3 with resistance 6 ohms + 12 ohms = 18 ohms. Thus, $\frac{1}{r_{12}} = \frac{1}{18} + \frac{1}{18} = \frac{1}{9}$, so $r_{12} = 9$ ohms. Similar computations show that the resistance between outlets 1 and 3 is 8 ohms and the resistance between outlets 2 and 3 is 5 ohms. The black-box matrix is $\begin{bmatrix} 0 & 9 & 8 \\ 9 & 0 & 5 \\ 8 & 5 & 0 \end{bmatrix}$.
2. Let us remark that the properties of the outlets of a black-box do not depend on the way the conductors and resistors in the box are set. Here is another way the black-box-matrix in

Example 1 could be obtained: There are no direct connections between nodes 1, 2, and 3, but there is a fourth node 4, which is connected with node 1 by a conductor of resistance 6 ohms, with node 2 by a conductor of resistance 3 ohms, and with node 3 by a conductor of resistance 2 ohms. Since resistors in series add, this produces the same black-box matrix. If we then connect the outlets 1 and 2 by a short-circuit (conductor of no resistance), in both cases the resulting resistance between the new outlet $\{1, 2\}$ and outlet 3 will be the same, equal to 4 ohms.

The topics of this chapter and the next (on group representations) are closely related. Here we consider some particular groups that arise most naturally as matrix groups or quotients of them, and special properties of matrix groups that are not shared by arbitrary groups. In representation theory, we consider what we learn about a group by considering all its homomorphisms to matrix groups. In this chapter we discuss properties of specific matrix groups, especially the general linear group (consisting of all invertible matrices of given size over a given field) and the related "classical groups." Most group theoretic terminology is standard and can be found in any textbook or in the Preliminaries of this book.

84.1 Introduction

Definitions:

The **general linear group** $\mathrm{GL}(n,F)$ is the group consisting of all invertible $n \times n$ matrices over the field F.

A **matrix group** is a subgroup of $\mathrm{GL}(n,F)$ for some natural number n and field F.

If V is a vector space of dimension n over F, the **group of invertible linear operators** on V is denoted by $\mathrm{GL}(V)$.

A **linear group** of **degree** n is a subgroup of $\mathrm{GL}(V)$ (where $\dim V = n$). (A subgroup of $\mathrm{GL}(n,F)$ is a linear group of degree n, since an $n \times n$ matrix can be viewed as a linear operator acting on F^n by matrix multiplication.)

A linear group $G \leq \mathrm{GL}(V)$ is said to be **reducible** if there is a G-invariant subspace U of V other than $\{0\}$ and V, and is **irreducible** otherwise. If $G \leq \mathrm{GL}(V)$ is irreducible, then V is called **G-irreducible**.

A linear group $G \leq \mathrm{GL}(V)$ is said to be **decomposable** if V is the direct sum of two nonzero G-invariant subspaces, and is **indecomposable** otherwise.

If V can be expressed as the direct sum of G-irreducible subspaces, then G is **completely reducible**. (An irreducible group is completely reducible.)

If the matrix group $G \leq \mathrm{GL}(n,F)$ is irreducible when regarded as a subgroup of $\mathrm{GL}(n,K)$ for any algebraic extension K of F, we say that G is **absolutely irreducible**.

A linear group of degree n is **unipotent** if all its elements have n eigenvalues equal to 1.

Let X and Y be group-theoretic properties.

A group G is **locally X** if every finite subset of G is contained in a subgroup with property X.

Facts:

For these facts and general background reading, see [Dix71], [Sup76], and [Weh73].

1. If V is a vector space of dimension n over F, then $\mathrm{GL}(V)$ is isomorphic to $\mathrm{GL}(n, F)$.
2. Every finite group is isomorphic to a matrix group.
3. Basic facts from linear algebra about similarity of matrices can be interpreted as statements about conjugacy classes in $\mathrm{GL}(n, F)$. For example:
   (a) Two nonsingular matrices are conjugate in $\mathrm{GL}(n, F)$ if and only if they have the same invariant factors.
   (b) If F is algebraically closed, then two nonsingular matrices are conjugate in $\mathrm{GL}(n, F)$ if and only if they have the same Jordan canonical form.
   (c) Two real symmetric matrices are conjugate in $\mathrm{GL}(n, \mathbb{R})$ if and only if they have the same rank and signature.

   (See Chapter 6 for more information on the Jordan canonical form and invariant factors and Chapter 13 for more information on signature.)
4. A matrix group G of degree n is reducible if and only if there exists a nonsingular matrix $M \in F^{n\times n}$ and k with $1 \leq k \leq n-1$ such that for all $A \in G, M^{-1}AM$ is of the form $\begin{bmatrix} B_{11} & B_{12} \\ \mathbf{0} & B_{22} \end{bmatrix}$, where $B_{11} \in F^{k\times k}, B_{22} \in F^{(n-k)\times(n-k)}$.
5. (See Chapter 85) The image of a representation of a group is a linear group. The image of a matrix representation of a group is a matrix group. We apply descriptions of the linear group to the representation: If $\rho : G \to \mathrm{GL}(V)$ is a representation, and $\rho(G)$ is irreducible, indecomposable, absolutely irreducible, etc., then we say that the representation ρ is irreducible, etc.
6. If every finitely generated subgroup of a group G is isomorphic to a linear group of degree n over a field F (of arbitrary characteristic), then G is isomorphic to a linear group of degree n.
7. Any free group is linear of degree 2 in every characteristic. More generally, a free product of linear groups is linear.
8. (Maschke's Theorem) Let G be a finite linear group over F, and suppose that the characteristic of F is either zero or coprime to $|G|$. If G is reducible, then it is decomposable.
9. A locally finite linear group in characteristic zero is completely reducible.
10. (Clifford's Theorem) Let G be an irreducible linear group on a vector space V of dimension n, and let N be a normal subgroup of G. Then V is a direct sum of minimal N-spaces $W_1, \ldots, W_d$ permuted transitively by G. In particular, d divides n, the group N is completely reducible, and the linear groups induced on W_i by N are all isomorphic.
11. A normal (or even a subnormal) subgroup of a completely reducible linear group is completely reducible.
12. A unipotent matrix group is conjugate (in the general linear group) to the group of upper unit triangular matrices.
13. A linear group G on V has a unipotent normal subgroup U such that G/U is isomorphic to a completely reducible linear group on V; the subgroup U is a nilpotent group of class at most $n-1$, where $n = \dim(V)$.
14. (Mal'cev) If every finitely generated subgroup of the linear group G is completely reducible, then G is completely reducible.

15. Let G be a linear group on F^n, where F is algebraically closed. Then G is irreducible if and only if the elements of G span the space $F^{n\times n}$ of all $n \times n$ matrices over F.

Examples:

1. The matrix group
$$G = \left\{ \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}, \begin{bmatrix} \frac{1}{3} & \frac{2}{3} \\ \frac{4}{3} & -\frac{1}{3} \end{bmatrix}, \begin{bmatrix} -\frac{1}{3} & -\frac{2}{3} \\ -\frac{4}{3} & \frac{1}{3} \end{bmatrix} \right\}$$
is decomposable and completely reducible: the subspaces of $\mathbb{R}^2$ spanned by the vectors $[1,1]^T$ and $[-1,2]^T$ are G-invariant. That is, with $M = \begin{bmatrix} 1 & -1 \\ 1 & 2 \end{bmatrix}$, for any $A \in G, M^{-1}AM$ is a diagonal matrix.
2. The matrix group
$$\left\{ \begin{bmatrix} 1 & a \\ 0 & 1 \end{bmatrix} : \ a \in \mathbb{R} \right\}$$
is reducible, but neither decomposable nor completely reducible.
3. The matrix group
$$\left\{ \begin{bmatrix} \cos x & \sin x \\ -\sin x & \cos x \end{bmatrix} : x \in \mathbb{R} \right\}$$
of real rotations is irreducible over $\mathbb{R}$ but not over $\mathbb{C}$: The subspace spanned by $[1, i]^T$ is invariant. The matrices in this group span the 2-dimensional subspace of $\mathbb{R}^{2\times 2}$ consisting of matrices $A = [a_{ij}]$ satisfying the equations $a_{11} = a_{22}$ and $a_{12} + a_{21} = 0$.
4. A group is locally finite if and only if every finitely generated subgroup is finite.

84.2 The General and Special Linear Groups

Definitions:

The **special linear group** $\mathrm{SL}(n, F)$ is the subgroup of $\mathrm{GL}(n, F)$ consisting of matrices of determinant 1. If V is a vector space of dimension n over F, the group of invertible linear operators on V having determinant 1 is denoted by $\mathrm{SL}(V)$.

The **special linear group** $\mathrm{SL}(n, F)$ is the subgroup of $\mathrm{GL}(n, F)$ consisting of matrices of determinant 1.

The **projective general linear group** and **projective special linear group** $\mathrm{PGL}(n, F)$ and $\mathrm{PSL}(n, F)$ are the quotients of $\mathrm{GL}(n, F)$ and $\mathrm{SL}(n, F)$ by their normal subgroups Z and $Z \cap \mathrm{SL}(n, F)$, respectively, where Z is the group of nonzero scalar matrices.

Notation: If $F = \mathrm{GF}(q)$ is the finite field of order q, then $\mathrm{GL}(n, F)$ is denoted $\mathrm{GL}(n, q)$, $\mathrm{SL}(n, F)$ is denoted $\mathrm{SL}(n, q)$, etc.

A **transvection** is a linear operator T on V with all eigenvalues equal to 1 and satisfying $\mathrm{rank}(T - I) = 1$.

Facts:

For these facts and general background reading see [HO89], [Tay92], or [Kra02].

1. The special linear group $\mathrm{SL}(n, F)$ is a normal subgroup of the general linear group $\mathrm{GL}(n, F)$.

2. The order of $\mathrm{GL}(n,q)$ is equal to the number of ordered bases of $\mathrm{GF}(q)^n$, namely
$$|\,\mathrm{GL}(n,q)| = \prod_{i=0}^{n-1}(q^n - q^i) = q^{n(n-1)/2}\prod_{i=0}^{n-1}(q^{n-i}-1).$$
3. A transvection has determinant 1, and so lies in $\mathrm{SL}(V)$.
4. A transvection on F^n has the form $I + \mathbf{v}\mathbf{w}^T$ for some $\mathbf{v},\mathbf{w} \in F^n$ and $\mathbf{w}^T\mathbf{v} = 0$, and anything in this form is a transvection.
5. A transvection T on V has the form $T : x \mapsto \mathbf{x} + f(\mathbf{x})\mathbf{v}$, where $\mathbf{v} \in V$, $f \in V^*$, and $f(\mathbf{v}) = 0$, and anything in this form is a transvection.
6. The group $\mathrm{SL}(n,F)$ is generated by transvections, for any $n \geq 2$ and any field F.
7. The group $\mathrm{PSL}(n,F)$ is simple for all $n \geq 2$ and all fields F, except for the two cases $\mathrm{PSL}(2,2)$ and $\mathrm{PSL}(2,3)$. The groups $\mathrm{PSL}(2,2)$ and $\mathrm{PSL}(2,3)$ are isomorphic to the symmetric group on 3 letters and the alternating group on 4 letters, respectively. The groups $\mathrm{PSL}(2,4)$ and $\mathrm{PSL}(2,5)$ are both isomorphic to the alternating group on 5 letters.

Examples:

1. $\mathrm{GL}(2,2) = \mathrm{SL}(2,2) = \mathrm{PSL}(2,2) =$
$$\left\{\begin{bmatrix}1&0\\0&1\end{bmatrix},\begin{bmatrix}1&1\\0&1\end{bmatrix},\begin{bmatrix}1&0\\1&1\end{bmatrix},\begin{bmatrix}0&1\\1&0\end{bmatrix},\begin{bmatrix}0&1\\1&0\end{bmatrix},\begin{bmatrix}0&1\\1&0\end{bmatrix}\right\}.$$
2. $\mathrm{SL}(2,3) =$
$$\left\{\begin{bmatrix}1&0\\0&1\end{bmatrix},\begin{bmatrix}1&1\\0&1\end{bmatrix},\begin{bmatrix}1&2\\0&1\end{bmatrix},\begin{bmatrix}1&0\\1&1\end{bmatrix},\begin{bmatrix}1&0\\2&1\end{bmatrix},\begin{bmatrix}2&0\\0&2\end{bmatrix},\begin{bmatrix}2&1\\0&2\end{bmatrix},\begin{bmatrix}2&2\\0&2\end{bmatrix},\right.$$
$$\left.\begin{bmatrix}2&0\\1&2\end{bmatrix},\begin{bmatrix}2&0\\2&2\end{bmatrix},\begin{bmatrix}1&1\\1&2\end{bmatrix},\begin{bmatrix}1&2\\2&2\end{bmatrix},\begin{bmatrix}2&1\\1&1\end{bmatrix},\begin{bmatrix}2&2\\2&1\end{bmatrix},\begin{bmatrix}0&1\\2&0\end{bmatrix},\begin{bmatrix}0&2\\1&0\end{bmatrix}\right\}.$$
3. $$T = \begin{bmatrix}-13&-10&-2\\14&11&2\\28&20&5\end{bmatrix}$$
is a transvection. $T = I + \mathbf{v}\mathbf{w}^T$ with $\mathbf{v} = [-2,2,4]^T$, and $\mathbf{w} = [7,5,1]^T$.

84.3 The BN Structure of the General Linear Group

Definitions:

A BN-**pair** (or **Tits system**) is an ordered quadruple (G,B,N,S) where

- G is a group generated by subgroups B and N.
- $T := B \cap N$ is normal in N.
- S is a subset of $W := N/T$ and S generates W.
- The elements of S are all of order 2.
- If $\rho,\sigma \in N$ and $\rho T \in S$, then $\rho B\sigma \subseteq B\sigma B \cup B\rho\sigma B$.
- If $\rho T \in S$, then $\rho B\rho \neq B$.

If (G, B, N, S) is a BN-pair, the subgroups B and $W = N/T$ are known as the **Borel subgroup** and **Weyl group** of G.

A **parabolic subgroup** of G (relative to a given BN-pair) is a subgroup of the form $P_I = \langle B, s_i : i \in I\rangle$ for some subset I of $\{1, \ldots, |S|\}$.

Facts:

For these facts and general background reading, see [HO89], [Tay92], or [Kra02].

1. The general linear group $\mathrm{GL}(n, F)$ with $n \geq 2$ has the following Tits system:
    - B is the group of upper-triangular matrices in G.
    - U is the group of unit upper-triangular matrices (with diagonal entries 1).
    - T is the group of diagonal matrices.
    - N is the group of matrices having a unique nonzero element in each row or column.
    - $S = \{s_i : i = 1, \ldots, n-1\}$, where $s_i = P_iT$ and P_i is the reflection which interchanges the ith and $(i+1)$st standard basis vectors (P_i is obtained from the identity matrix by interchanging rows i and $i+1$).
    - N is the normalizer of T in $\mathrm{GL}(n, F)$.
    - $B = UT$.
    - $B \cap N = T$.
    - N/T is isomorphic to the symmetric group S_n.
2. If G has a BN-pair, any subgroup of G containing B is a parabolic subgroup.
3. In $\mathrm{GL}(n, F)$, there are 2^{n-1} parabolic subgroups for the BN-pair in Fact 1, hence, there are 2^{n-1} subgroups of $\mathrm{GL}(n, F)$ containing the subgroup B of upper-triangular matrices.
4. More generally, with respect to any basis of V there is a BN-structure. The terms *Borel subgroup* and *parabolic subgroup* are used to refer to the subgroups defined with respect to an arbitrary basis. All the Borel subgroups of $\mathrm{GL}(V)$ are conjugate. The maximal parabolic subgroups are precisely the maximal reducible subgroups.

Examples:

1. The maximal parabolic subgroups of $\mathrm{GL}(n, F)$ with the BN-pair in Fact 1 are those for which $I = \{1, \ldots, n-1\} \setminus \{k\}$ for some k; it is easy to see that in this case P_I is the stabilizer of the subspace spanned by the first k basis vectors. This subgroup consists of all matrices with block form as in Fact 84.1.4.

84.4 Classical Groups

The classical groups form several important families of linear groups. We give a brief description here, and refer to the books [HO89], [Tay92], or the article [Kra02] for more details. For information on bilinear, sesquilinear, and quadratic forms, see Chapter 13.

Definitions:

A φ-sesquilinear form B is **φ-Hermitian** if $B(\mathbf{v}, \mathbf{w}) = \varphi(B(\mathbf{w}, \mathbf{v}))$ for all $\mathbf{v}, \mathbf{w} \in V$. In the case where $F = \mathbb{C}$ and φ is conjugation, a φ-Hermitian form is called a **Hermitian** form.

A **formed space** is a finite dimensional vector space carrying a nondegenerate φ-Hermitian, symmetric, or alternating form B.

A **classical group** over a formed space V is the subgroup of $\mathrm{GL}(V)$ consisting of the linear operators that preserve the form. We distinguish three types of classical groups:

1. **Orthogonal group:** Preserving a nondegenerate symmetric bilinear form B.
2. **Symplectic group:** Preserving a nondegenerate alternating bilinear form B.
3. **Unitary group:** Preserving a nondegenerate σ-Hermitian form B, with $\sigma \neq 1$.

We denote a classical subgroup of $\mathrm{GL}(V)$ by $\mathrm{O}(V)$, $\mathrm{Sp}(V)$, or $\mathrm{U}(V)$ depending on type. If necessary, we add extra notation to specify which particular form is being used. If $V = F^n$, we also write $\mathrm{O}(n, F)$, $\mathrm{Sp}(n, F)$, or $\mathrm{U}(n, F)$.

The **Witt index** of a formed space V is the dimension of the largest subspace on which the form is identically zero. The Witt index of the corresponding classical group is the Witt index of the formed space.

An **isometry** between subspaces of a formed space is a linear transformation preserving the value of the form.

A representation of a group G over the complex numbers is said to be **unitary** if its image is contained in the unitary group.

Facts:

For these facts and for general background reading, see [HO89], [Tay92], or [Kra02].

1. The only automorphism of $\mathbb{R}$ is the identity, so any sesquilinear form on a real vector space is bilinear and any φ-Hermitian form is symmetric. A real formed space has a symmetric or alternating bilinear form as its form. The classical subgroups of a real formed space are orthogonal or symplectic.
2. The only automorphisms of $\mathbb{C}$ that preserve the reals are the identity and complex conjugation. Any φ-Hermitian form such that φ preserves the reals is a Hermitian form.
3. Classification of classical groups up to conjugacy in $\mathrm{GL}(n, F)$ is equivalent to classification of forms of the appropriate type up to the natural action of the general linear group together with scalar multiplication. Often this is a very difficult problem; the next fact gives a few cases where the classification is more straightforward.
4. (a) A nondegenerate alternating form on $V = F^n$ exists if and only if n is even, and all such forms are equivalent. So there is a unique conjugacy class of symplectic groups in $\mathrm{GL}(n, F)$ if n is even (with Witt index $n/2$), and none if n is odd.
   (b) Let $F = \mathrm{GF}(q)$. Then, up to conjugacy, $\mathrm{GL}(n, q)$ contains one conjugacy class of unitary subgroups (with Witt index $\lfloor n/2 \rfloor$), one class of orthogonal subgroups if n is odd (with Witt index $(n-1)/2$), and two classes if n is even (with Witt indices $n/2$ and $n/2 - 1$).
   (c) A nondegenerate symmetric bilinear form on $\mathbb{R}^n$ is determined up to the action of $\mathrm{GL}(n, \mathbb{R})$ by its signature. Its Witt index is $\min\{s, t\}$, where s and t are the numbers of positive and negative eigenvalues. So there are $\lfloor n/2 \rfloor + 1$ conjugacy classes of orthogonal subgroups of $\mathrm{GL}(n, \mathbb{R})$, with Witt indices $0, 1, \ldots, \lfloor n/2 \rfloor$.
5. (Witt's Lemma) Suppose that U_1 and U_2 are subspaces of the formed space V, and $h : U_1 \to U_2$ is an isometry. Then there is an isometry g of V that extends h.
6. From Witt's Lemma it is possible to write down formulas for the orders of the classical groups over finite fields similar to the formula in Fact 2 general linear group.
7. The analogues of Facts 84.2.6 and 84.2.7 hold for the classical groups with nonzero Witt index. However, the situation is more complicated. Any symplectic transformation has determinant 1, so $\mathrm{Sp}(2r, F) \leq \mathrm{SL}(2r, F)$. Moreover, $\mathrm{Sp}(2r, F)$ is generated by symplectic transvections (those preserving the alternating form) for $r \geq 2$, except for $\mathrm{Sp}(4, 2)$. Similarly, the *special unitary group* $\mathrm{SU}(n, F)$ (the intersection of $\mathrm{U}(n, F)$

with $\mathrm{SL}(n, F)$) with positive Witt index is generated by unitary transvections (those preserving the Hermitian form), except for $\mathrm{SU}(3, 2)$. Results for orthogonal groups are more difficult. See [HO89] for more information.

8. Like the general linear groups, the classical groups contain BN-pairs (configurations of subgroups satisfying conditions like those in the previous section). The difference is that the Weyl group $W = N/H$ is not the symmetric group, but one of the other types of Coxeter group (finite groups generated by reflections).
9. Although this treatment of classical groups has been as far as possible independent of fields, for most of mathematics, the classical groups over the real and complex numbers are the most important, and among these, the real orthogonal and complex unitary groups preserving positive definite forms are the most important; see [Wey39].
10. The theory can be extended to classical groups over rings. This has important connections with algebraic K-theory. The book [HO89] gives details.
11. Every representation of a finite group is equivalent to a unitary representation.

Examples:

1. The function B given by $B((x_1, y_1), (x_2, y_2)) = x_1y_2 - x_2y_1$ is an alternating bilinear form on F^2. Any matrix with determinant 1 will preserve this form. So $Sp(2, F) = SL(2, F)$.
2. The symmetric group S_6 acts on F^6, where F is the field with two elements. It preserves the 1-dimensional subspace U spanned by (1, 1, 1, 1, 1, 1), as well as the 5-dimensional subspace consisting of vectors with coordinate sum zero. The usual dot product on F^6 is alternating when restricted to W, and its radical is U, so it induces a symplectic form on W/U. Thus, S_6 is a subgroup of the symplectic group $Sp(4, 2)$. Since both groups have order 720, we see that $Sp(4, 2) = S_6$.

Representation theory is the study of the various ways a given group can be mapped into a general linear group. This information has proven to be effective at providing insight into the structure of the given group as well as the objects on which the group acts. Most notable is the central contribution made by representation theory to the complete classification of finite simple groups [Gor94]. (See also Fact 85.1.3 and Fact 85.6.5.)

Representations of finite groups can be defined over an arbitrary field and such have been studied extensively. Here, however, we discuss only the most widely used, classical theory of representations over the field of complex numbers (many results of which fail to hold over other fields).

85.1 Basic Concepts

Throughout, G denotes a finite group, e denotes its identity element, and V denotes a finite dimensional complex vector space.

Definitions:

The **general linear group** of a vector space V is the group $GL(V)$ of linear isomorphisms of V onto itself with operation given by function composition.

A (**linear**) **representation** of the finite group G (over the complex field $\mathbb{C}$) is a homomorphism $\rho = \rho_V : G \to GL(V)$, where V is a finite dimensional vector space over $\mathbb{C}$.

The **degree** of a representation ρ_V is the dimension of the vector space V.

Two representations $\rho : G \to GL(V)$ and $\rho' : G \to GL(V')$ are **equivalent** (or **isomorphic**) if there exists a linear isomorphism $\tau : V \to V'$ such that $\tau \circ \rho(s) = \rho'(s) \circ \tau$ for all $s \in G$.

Given a representation ρ_V of G, a subspace W of V is G**-stable** (or G**-invariant**) if $\rho_V(s)(W) \subseteq W$ for all $s \in G$.

If ρ_V is a representation of G and W is a G-stable subspace of V, then the induced maps $\rho_W : G \to GL(W)$ and $\rho_{V/W} : G \to GL(V/W)$ are the corresponding **subrepresentation** and **quotient representation**, respectively.

A representation ρ_V of G with $V \neq \{0\}$ is **irreducible** if V and $\{0\}$ are the only G-stable subspaces of V; otherwise, ρ_V is **reducible**.

The **kernel** of a representation ρ_V of G is the set of all $s \in G$ for which $\rho_V(s) = 1_V$.

A representation of G is **faithful** if its kernel consists of the identity element alone.

An **action** of G on a set X is a function $G \times X \to X$, $(s, x) \mapsto sx$, satisfying

- $(st)x = s(tx)$ for all $s, t \in G$ and $x \in X$,
- $ex = x$ for all $x \in X$.

A **$\mathbb{C}G$-module** is a finite-dimensional vector space V over $\mathbb{C}$ together with an action $(s, v) \mapsto sv$ of G on V that is linear in the variable v, meaning

- $s(v + w) = sv + sw$ for all $s \in G$ and $v, w \in V$,
- $s(\alpha v) = \alpha(sv)$ for all $s \in G$, $v \in V$ and $\alpha \in \mathbb{C}$.

(See Fact 6 below.)

Facts:

The following facts can be found in [Isa94, pp. 4–10] or [Ser77, pp. 3–13, 47].

1. If $\rho = \rho_V$ is a representation of G, then
   (a) $\rho(e) = 1_V$,
   (b) $\rho(st) = \rho(s)\rho(t)$ for all $s, t \in G$,
   (c) $\rho(s^{-1}) = \rho(s)^{-1}$ for all $s \in G$.
2. A representation of G of degree one is a group homomorphism from G into the group $\mathbb{C}^\times$ of nonzero complex numbers under multiplication (identifying $\mathbb{C}^\times$ with $GL(\mathbb{C})$). Every representation of degree one is irreducible.
3. The group G is abelian if and only if every irreducible representation of G is of degree one.
4. *Maschke's Theorem*: If ρ_V is a representation of G and W is a G-stable subspace of V, then there exists a G-stable vector space complement of W in V.
5. *Schur's Lemma*: Let $\rho : G \to GL(V)$ and $\rho' : G \to GL(V')$ be two irreducible representations of G and let $f : V \to V'$ be a linear map satisfying $f \circ \rho(s) = \rho'(s) \circ f$ for all $s \in G$.
   (a) If ρ' is not equivalent to ρ, then f is the zero map.
   (b) If $V' = V$ and $\rho' = \rho$, then f is a scalar multiple of the identity map: $f = \alpha 1_V$ for some $\alpha \in \mathbb{C}$.
6. If $\rho = \rho_V$ is a representation of G, then V becomes a $\mathbb{C}G$-module with action given by $sv = \rho(s)(v)$ ($s \in G$, $v \in V$). Conversely, if V is a $\mathbb{C}G$-module, then $\rho_V(s)(v) = sv$ defines a representation $\rho_V : G \to GL(V)$ (called the *representation of G afforded by V*). The study of representations of the finite group G is the same as the study of $\mathbb{C}G$-modules.
7. The vector space $\mathbb{C}G$ over $\mathbb{C}$ with basis G is a ring (the *group ring* of G over $\mathbb{C}$) with multiplication obtained by linearly extending the operation in G to arbitrary products. If V is a $\mathbb{C}G$-module and the action of G on V is extended linearly to a map $\mathbb{C}G \times V \to V$, then V becomes a (left unitary) $\mathbb{C}G$-module in the ring theoretic sense, that is, V satisfies the usual vector space axioms (see Section 1.1) with the scalar field replaced by the ring $\mathbb{C}G$.

Examples:

See also examples in the next section.

1. Let $n \in \mathbf{N}$ and let $\omega \in \mathbb{C}$ be an nth root of unity (meaning $\omega^n = 1$). Then the map $\rho : \mathbf{Z}_n \to \mathbb{C}^\times$ given by $\rho(m) = \omega^m$ is a representation of degree one of the group $\mathbf{Z}_n$ of integers modulo n. It is irreducible.
2. *Regular representation*: Let $V = \mathbb{C}G$ be the complex vector space with basis G. For each $s \in G$ there is a unique linear map $\rho(s) : V \to V$ satisfying $\rho(s)(t) = st$ for all $t \in G$. Then $\rho : G \to GL(V)$ is a representation of G called the *(left) regular representation.* If $|G| > 1$, then the regular representation is reducible (see Example 85.5.3).
3. *Permutation representation*: Let X be a finite set, let $(s, x) \mapsto sx$ be an action of G on X, and let V be the complex vector space with basis X. For each $s \in G$ there is a unique linear map $\rho(s) : V \to V$ satisfying $\rho(s)(x) = sx$ for all $x \in X$. Then $\rho : G \to GL(V)$ is a representation of G called a *permutation representation.* The regular representation of G (Example 2) is the permutation representation corresponding to the action of G on itself given by left multiplication.
4. The representation of G of degree 1 given by $\rho(s) = 1 \in \mathbb{C}^\times$ for all $s \in G$ is the *trivial representation.*
5. *Direct sum*: If V and W are $\mathbb{C}G$-modules, then the $\mathbb{C}$-vector space direct sum $V \oplus W$ is a $\mathbb{C}G$-module with action given by $s(v, w) = (sv, sw)$ $(s \in G,\ v \in V,\ w \in W)$.
6. *Tensor product*: If V_1 is a $\mathbb{C}G_1$-module and V_2 is a $\mathbb{C}G_2$-module, then the $\mathbb{C}$-vector space tensor product $V_1 \otimes V_2$ is a $\mathbb{C}(G_1 \times G_2)$-module with action given by $(s_1, s_2)(v_1 \otimes v_2) = (s_1 v_1) \otimes (s_2 v_2)$ $(s_i \in G_i,\ v_i \in V_i)$. If both groups G_1 and G_2 equal the same group G, then $V_1 \otimes V_2$ is a $\mathbb{C}G$-module with action given by $s(v_1 \otimes v_2) = (sv_1) \otimes (sv_2)$ $(s \in G,\ v_i \in V_i)$.
7. *Contragredient*: If V is a $\mathbb{C}G$-module, then the $\mathbb{C}$-vector space dual V^* is a $\mathbb{C}G$-module (called the *contragredient* of V) with action given by $(sf)(v) = f(s^{-1}v)$ $(s \in G,\ f \in V^*,\ v \in V)$.

85.2 Matrix Representations

Throughout, G denotes a finite group, e denotes its identity element, and V denotes a finite dimensional complex vector space.

Definitions:

A **matrix representation** of G of **degree** n (over the field $\mathbb{C}$) is a homomorphism $R : G \to GL_n(\mathbb{C})$, where $GL_n(\mathbb{C})$ is the group of nonsingular $n \times n$ matrices over the field $\mathbb{C}$. (For the relationship between representations and matrix representations, see the following Facts.)

The **empty matrix** is a 0×0 matrix having no entries. The trace of the empty matrix is 0. $GL_0(\mathbb{C})$ is the trivial group whose only element is the empty matrix.

Two matrix representations R and R' are **equivalent** (or **isomorphic**) if they have the same degree, say n, and there exists a nonsingular $n \times n$ matrix P such that $R'(s) = PR(s)P^{-1}$ for all $s \in G$.

A matrix representation of G is **reducible** if it is equivalent to a matrix representation R having the property that for each $s \in G$, the matrix $R(s)$ has the block form

$$R(s) = \begin{bmatrix} X(s) & Z(s) \\ 0 & Y(s) \end{bmatrix}$$

(block sizes independent of s).

A matrix representation is **irreducible** if it has nonzero degree and it is not reducible.

The **kernel** of a matrix representation R of G of degree n is the set of all $s \in G$ for which $R(s) = I_n$.

A matrix representation of G is **faithful** if its kernel consists of the identity element alone.

Facts:

The following facts can be found in [Isa94, pp. 10–11, 32] or [Ser77, pp. 11–14].

1. If R is a matrix representation of G, then
   (a) $R(e) = I$,
   (b) $R(st) = R(s)R(t)$ for all $s, t \in G$,
   (c) $R(s^{-1}) = R(s)^{-1}$ for all $s \in G$.
2. If $\rho = \rho_V$ is a representation of G of degree n and $\mathcal{B}$ is an ordered basis for V, then $R_{\rho,\mathcal{B}}(s) = [\rho(s)]_{\mathcal{B}}$ defines a matrix representation $R_{\rho,\mathcal{B}} : G \to GL_n(\mathbb{C})$ called the *matrix representation of* G *afforded by the representation* ρ (or *by the* $\mathbb{C}G$*-module* V) *with respect to the basis* $\mathcal{B}$. Conversely, if R is a matrix representation of G of degree n and $V = \mathbb{C}^n$, then $\rho(s)(v) = R(s)v$ ($s \in G$, $v \in V$) defines a representation ρ of G and $R = R_{\rho,\mathcal{B}}$, where $\mathcal{B}$ is the standard ordered basis of V.
3. If R and R' are matrix representations afforded by representations ρ and ρ', respectively, then R and R' are equivalent if and only if ρ and ρ' are equivalent. In particular, two matrix representations that are afforded by the same representation are equivalent regardless of the chosen bases.
4. If $\rho = \rho_V$ is a representation of G and W is a G-stable subspace of V and a basis for W is extended to a basis $\mathcal{B}$ of V, then for each $s \in G$ the matrix $R_{\rho,\mathcal{B}}(s)$ is of block form
$$R_{\rho,\mathcal{B}}(s) = \begin{bmatrix} X(s) & Z(s) \\ 0 & Y(s) \end{bmatrix},$$
where X and Y are the matrix representations afforded by ρ_W (with respect to the given basis) and $\rho_{V/W}$ (with respect to the induced basis), respectively.
5. If the matrix representation R of G is afforded by a representation ρ, then R is irreducible if and only if ρ is irreducible.
6. The group G is Abelian if and only if every irreducible matrix representation of G is of degree one.
7. *Maschke's Theorem* (*for matrix representations*): If R is a matrix representation of G and for each $s \in G$ the matrix $R(s)$ is of block form
$$R(s) = \begin{bmatrix} X(s) & Z(s) \\ 0 & Y(s) \end{bmatrix}$$
(block sizes independent of s), then R is equivalent to the matrix representation R' given by
$$R'(s) = \begin{bmatrix} X(s) & 0 \\ 0 & Y(s) \end{bmatrix}$$
($s \in G$).
8. *Schur relations*: Let R and R' be irreducible matrix representations of G of degrees n and n', respectively. For $1 \leq i, j \leq n$ and $1 \leq i', j' \leq n'$ define functions $r_{ij}, r'_{i'j'} : G \to \mathbb{C}$ by $R(s) = [r_{ij}(s)]$, $R'(s) = [r'_{i'j'}(s)]$ ($s \in G$).
   (a) If R' is not equivalent to R, then for all $1 \leq i, j \leq n$ and $1 \leq i', j' \leq n'$
$$\sum_{s \in G} r_{ij}(s^{-1}) r'_{i'j'}(s) = 0.$$
   (b) For all $1 \leq i, j, k, l \leq n$
$$\sum_{s \in G} r_{ij}(s^{-1}) r_{kl}(s) = \begin{cases} |G|/n & \text{if } i = l \text{ and } j = k \\ 0 & \text{otherwise.} \end{cases}$$

Examples:

1. An example of a degree two matrix representation of the symmetric group S_3 is given by

$$R(e) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \qquad R(12) = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \qquad R(23) = \begin{bmatrix} -1 & -1 \\ 0 & 1 \end{bmatrix},$$

$$R(13) = \begin{bmatrix} 1 & 0 \\ -1 & -1 \end{bmatrix}, \quad R(123) = \begin{bmatrix} 0 & 1 \\ -1 & -1 \end{bmatrix}, \quad R(132) = \begin{bmatrix} -1 & -1 \\ 1 & 0 \end{bmatrix}.$$

   (Cf. Example 85.4.2.)

2. The matrix representation R of the additive group $\mathbf{Z}_3$ of integers modulo 3 afforded by the regular representation with respect to the basis $\mathbf{Z}_3 = \{0, 1, 2\}$ (ordered as indicated) is given by

$$R(0) = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad R(1) = \begin{bmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}, \quad R(2) = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}.$$

3. Let $\rho : G \to GL(V)$ and $\rho' : G \to GL(V')$ be two representations of G, let $\mathcal{B}$ and $\mathcal{B}'$ be bases of V and V', respectively, and let $R = R_{\rho,\mathcal{B}}$ and $R' = R_{\rho',\mathcal{B}'}$ be the afforded matrix representations.

   (a) The matrix representation afforded by the direct sum $V \oplus V'$ with respect to the basis $\{(b, 0), (0, b') \,|\, b \in \mathcal{B}, b' \in \mathcal{B}'\}$ is given by $s \mapsto R(s) \oplus R'(s)$ (direct sum of matrices).

   (b) The matrix representation afforded by the tensor product $V \otimes V'$ with respect to the basis $\{b \otimes b' \,|\, b \in \mathcal{B}, b' \in \mathcal{B}'\}$ is given by $s \mapsto R(s) \otimes R'(s)$ (Kronecker product of matrices).

   (c) The matrix representation afforded by the contragredient V^* with respect to the dual basis of $\mathcal{B}$ is given by $s \mapsto (R(s)^{-1})^T$ (inverse transpose of matrix).

85.3 Characters

Throughout, G denotes a finite group, e denotes its identity element, and V denotes a finite dimensional complex vector space.

Definitions:

The **character of G afforded by a matrix representation** R of G is the function $\chi : G \to \mathbb{C}$ defined by $\chi(s) = \operatorname{tr} R(s)$.

The **character of G afforded by a representation** $\rho = \rho_V$ of G is the character afforded by the corresponding matrix representation $R_{\rho,\mathcal{B}}$, where $\mathcal{B}$ is a basis for V.

The **character of G afforded by a $\mathbb{C}G$-module** V is the character afforded by the corresponding representation ρ_V.

An **irreducible character** is a character afforded by an irreducible representation.

The **degree** of a character χ of G is the number $\chi(e)$.

A **linear character** is a character of degree one.

If χ_1 and χ_2 are two characters of G, their **sum** is defined by $(\chi_1 + \chi_2)(s) = \chi_1(s) + \chi_2(s)$ and their **product** is defined by $(\chi_1\chi_2)(s) = \chi_1(s)\chi_2(s)$ $(s \in G)$.

If χ is a character of G, its **complex conjugate** is defined by $\overline{\chi}(s) = \overline{\chi(s)}$ $(s \in G)$, where $\overline{\chi(s)}$ denotes the conjugate of the complex number $\chi(s)$.

The **kernel** of a character χ of G is the set $\{s \in G \,|\, \chi(s) = \chi(e)\}$.

A character χ of G is **faithful** if its kernel consists of the identity element alone.

The **principal character** of G is the character 1_G satisfying $1_G(s) = 1$ for all $s \in G$.

The **zero character** of G is the character 0_G satisfying $0_G(s) = 0$ for all $s \in G$.

If χ and ψ are two characters of G, then ψ is called a **constituent** of χ if $\chi = \psi + \psi'$ with ψ' a character (possibly zero) of G.

Facts:

The following facts can be found in [Isa94, pp. 14–23, 38–40, 59] or [Ser77, pp. 10–19, 27, 52].

1. The principal character of G is the character afforded by the representation of G that maps every $s \in G$ to $[1] \in GL_1(\mathbb{C})$. The zero character of G is the character afforded by the representation of G that maps every $s \in G$ to the empty matrix in $GL_0(\mathbb{C})$.
2. The degree of a character of G equals the dimension of V, where ρ_V is a representation affording the character.
3. If χ is a character of G, then $\chi(s^{-1}) = \overline{\chi(s)}$ and $\chi(t^{-1}st) = \chi(s)$ for all $s, t \in G$.
4. Two characters of G are equal if and only if representations affording them are equivalent.
5. The number of distinct irreducible characters of G is the same as the number of conjugacy classes of G.
6. Every character χ of G can be expressed in the form $\chi = \sum_{\varphi \in Irr(G)} m_\varphi \varphi$, where $Irr(G)$ denotes the set of irreducible characters of G and where each m_φ is a nonnegative integer (called the *multiplicity* of φ as a constituent of χ).
7. A nonzero character of G is irreducible if and only if it is not the sum of two nonzero characters of G.
8. The kernel of a character equals the kernel of a representation affording the character.
9. The degree of an irreducible character of G divides the order of G.
10. A character of G is linear if and only if it is a homomorphism from G into the multiplicative group of nonzero complex numbers under multiplication.
11. The group G is abelian if and only if every irreducible character of G is linear.
12. The sum of the squares of the irreducible character degrees equals the order of G.
13. *Irreducible characters of direct products*: Let G_1 and G_2 be finite groups. Denoting by $Irr(G)$ the set of irreducible characters of the group G, we have $Irr(G_1 \times G_2) = Irr(G_1) \times Irr(G_2)$, where an element (χ_1, χ_2) of the Cartesian product on the right is viewed as a function on the direct product $G_1 \times G_2$ via $(\chi_1, \chi_2)(s_1, s_2) = \chi_1(s_1)\chi_2(s_2)$.
14. *Burnside's Vanishing Theorem*: If χ is a nonlinear irreducible character of G, then $\chi(s) = 0$ for some $s \in G$.

Examples:

See also examples in the next section.

1. If V_1 and V_2 are $\mathbb{C}G$-modules and χ_1 and χ_2, respectively, are the characters of G they afford, then the direct sum $V_1 \oplus V_2$ affords the sum $\chi_1 + \chi_2$ and the tensor product $V_1 \otimes V_2$ affords the product $\chi_1\chi_2$.
2. If V is a $\mathbb{C}G$-module and χ is the character it affords, then the contragredient V^* affords the complex conjugate character $\overline{\chi}$.
3. Let X be a finite set on which an action of G is given and let ρ be the corresponding permutation representation of G (see Example 85.1.3). If χ is the character afforded by ρ, then for each $s \in G$, $\chi(s)$ is the number of ones on the main diagonal of the permutation matrix $[\rho(s)]_X$, which is the same as the number of fixed points of X under the action of s: $\chi(s) = |\{x \in X \mid sx = x\}|$. The matrix representation of $\mathbf{Z}_3$ given in Example 85.2.2 is afforded by a permutation representation, namely, the regular representation; it affords

the character χ given by $\chi(0) = 3$, $\chi(1) = 0$, $\chi(2) = 0$ in accordance with the previous statement.

85.4 Orthogonality Relations and Character Table

Throughout, G denotes a finite group, e denotes its identity element, and V denotes a finite dimensional complex vector space.

Definitions:

A function $f : G \to \mathbb{C}$ is called a **class function** if it is constant on the conjugacy classes of G, that is, if $f(t^{-1}st) = f(s)$ for all $s, t \in G$.

The **inner product** of two functions f and g from G to $\mathbb{C}$ is the complex number

$$(f, g)_G = \frac{1}{|G|} \sum_{s \in G} f(s)\overline{g(s)}.$$

The **character table** of the group G is the square array with entry in the ith row and jth column equal to the complex number $\chi_i(c_j)$, where $Irr(G) = \{\chi_1, \ldots, \chi_k\}$ is the set of distinct irreducible characters of G and $\{c_1, \ldots, c_k\}$ is a set consisting of exactly one element from each conjugacy class of G.

Facts:

The following facts can be found in [Isa94, pp. 14–21, 30] or [Ser77, pp. 10–19].

1. Each character of G is a class function.
2. *First Orthogonality Relation*: If φ and ψ are two irreducible characters of G, then

$$(\phi, \psi)_G = \frac{1}{|G|} \sum_{s \in G} \varphi(s)\overline{\psi(s)} = \begin{cases} 1 & \text{if } \varphi = \psi \\ 0 & \text{if } \varphi \neq \psi. \end{cases}$$

3. *Second Orthogonality Relation*: If s and t are two elements of G, then

$$\sum_{\chi \in Irr(G)} \chi(s)\overline{\chi(t)} = \begin{cases} |G|/c(s) & \text{if } t \text{ is conjugate to } s \\ 0 & \text{if } t \text{ is not conjugate to } s, \end{cases}$$

   where $c(s)$ denotes the number of elements in the conjugacy class of s.
4. *Generalized Orthogonality Relation*: If φ and ψ are two irreducible characters of G and t is an element of G, then

$$\frac{1}{|G|} \sum_{s \in G} \varphi(st)\overline{\psi(s)} = \begin{cases} \varphi(t)/\varphi(e) & \text{if } \varphi = \psi \\ 0 & \text{if } \varphi \neq \psi. \end{cases}$$

   This generalizes the First Orthogonality Relation (Fact 2).
5. The set of complex-valued functions on G is a complex inner product space with inner product as defined above. The set of class functions on G is a subspace.
6. A character χ of G is irreducible if and only if $(\chi, \chi)_G = 1$.
7. The set $Irr(G)$ of irreducible characters of G is an orthonormal basis for the inner product space of class functions on G.

8. If the character χ of G is expressed as a sum of irreducible characters (see Fact 85.3.6), then the number of times the irreducible character φ appears as a summand is $(\chi, \varphi)_G$. In particular, $\varphi \in Irr(G)$ is a constituent of χ if and only if $(\chi, \varphi)_G \neq 0$.
9. Isomorphic groups have identical character tables (up to a reordering of rows and columns). The converse of this statement does not hold since, for example, the dihedral group and the quaternion group (both of order eight) have the same character table, yet they are not isomorphic.

Examples:

1. The character table of the group $\mathbf{Z}_4$ of integers modulo four is

	0	1	2	3
χ_0	1	1	1	1
χ_1	1	i	-1	$-i$
χ_2	1	-1	1	-1
χ_3	1	$-i$	-1	i

2. The character table of the symmetric group S_3 is

	(1)	(12)	(123)
χ_0	1	1	1
χ_1	1	-1	1
χ_2	2	0	-1

Note that χ_2 is the character afforded by the matrix representation of S_3 given in Example 85.2.1.

3. The character table of the symmetric group S_4 is

	(1)	(12)	(12)(34)	(123)	(1234)
χ_0	1	1	1	1	1
χ_1	1	-1	1	1	-1
χ_2	2	0	2	-1	0
χ_3	3	1	-1	0	-1
χ_4	3	-1	-1	0	1

4. The character table of the alternating group A_4 is

	(1)	(12)(34)	(123)	(132)
χ_0	1	1	1	1
χ_1	1	1	ω	ω^2
χ_2	1	1	ω^2	ω
χ_3	3	-1	0	0

where $\omega = e^{2\pi i/3} = -\frac{1}{2} + i\frac{\sqrt{3}}{2}$.

5. Let ρ_V be a representation of G and for each irreducible character φ of G put

$$T_\varphi = \frac{\varphi(e)}{|G|} \sum_{s \in G} \varphi(s^{-1}) \rho_V(s) : V \to V.$$

Then the Generalized Orthogonality Relation (Fact 4) shows that

$$T_\varphi T_\psi = \begin{cases} T_\varphi & \text{if } \varphi = \psi \\ 0 & \text{if } \varphi \neq \psi \end{cases}$$

and

$$\sum_{\varphi \in Irr(G)} T_\varphi = 1_V,$$

where 1_V denotes the identity operator on V. Moreover, $V = \bigoplus_{\varphi \in Irr(G)} T_\varphi(V)$ (internal direct sum).

85.5 Restriction and Induction of Characters

Throughout, G denotes a finite group, e denotes its identity element, and V denotes a finite dimensional complex vector space.

Definitions:

If χ is a character of G and H is a subgroup of G, then the **restriction** of χ to H is the character χ_H of H obtained by restricting the domain of χ.

A character φ of a subgroup H of G is **extendible** to G if $\varphi = \chi_H$ for some character χ of G.

If φ is a character of a subgroup H of G, then the **induced character** from H to G is the character φ^G of G given by the formula

$$\varphi^G(s) = \frac{1}{|H|} \sum_{t \in G} \varphi^\circ(t^{-1}st),$$

where φ° is defined by $\varphi^\circ(x) = \varphi(x)$ if $x \in H$ and $\varphi^\circ(x) = 0$ if $x \notin H$.

If φ is a character of a subgroup H of G and s is an element of G, then the **conjugate character** of φ by s is the character φ^s of $H^s = s^{-1}Hs$ given by $\varphi^s(h^s) = \varphi(h)$ $(h \in H)$, where $h^s = s^{-1}hs$.

Facts:

The following facts can be found in [Isa94, pp. 62–63, 73–79] or [Ser77, pp. 55–58].

1. The restricted character defined above is indeed a character: χ_H is afforded by the restriction to H of a representation affording χ.
2. The induced character defined above is indeed a character: Let V be a $\mathbb{C}H$-module affording φ and put $V^G = \bigoplus_{t \in T} V_t$, where $G = \bigcup_{t \in T} tH$ (disjoint union) and $V_t = V$ for each t. Then V^G is a $\mathbb{C}G$-module that affords φ^G, where the action is given as follows: For $s \in G$ and $v \in V_t$, sv is the element hv of $V_{t'}$, where $st = t'h$ $(t' \in T$, $h \in H)$.
3. The conjugate character defined above is indeed a character: φ^s is afforded by the representation of H^s obtained by composing the homomorphism $H^s \to H$, $h^s \mapsto h$ with a representation affording φ.
4. *Additivity of restriction*: Let H be a subgroup of G. If χ and χ' are characters of G, then $(\chi + \chi')_H = \chi_H + \chi'_H$.
5. *Additivity of induction*: Let H be a subgroup of G. If φ and φ' are characters of H, then $(\varphi + \varphi')^G = \varphi^G + \varphi'^G$.
6. *Transitivity of induction*: Let H and K be subgroups of G with $H \subseteq K$. If φ is a character of H, then $(\varphi^K)^G = \varphi^G$.
7. *Degree of induced character*: If H is a subgroup of G and φ is a character of H, then the degree of the induced character φ^G equals the product of the index of H in G and the degree of $\varphi : \varphi^G(e) = [G : H]\varphi(e)$.
8. Let χ be a character of G and let H be a subgroup of G. If the restriction χ_H is irreducible, then so is χ. The converse of this statement does not hold. In fact, if H is the trivial subgroup, then $\chi_H = \chi(e)1_H$, so any nonlinear irreducible character (e.g., χ_2 in Example 85.4.2) provides a counterexample.

9. Let H be a subgroup of G and let φ be a character of H. If the induced character φ^G is irreducible, then so is φ. The converse of this statement does not hold (see Example 3).
10. Let H be a subgroup of G. If φ is an irreducible character of H, then there exists an irreducible character χ of G such that φ is a constituent of χ_H.
11. *Frobenius Reciprocity*: If χ is a character of G and φ is a character of a subgroup H of G, then $(\varphi^G, \chi)_G = (\varphi, \chi_H)_H$.
12. If χ is a character of G and φ is a character of a subgroup H of G, then $(\varphi\chi_H)^G = \varphi^G\chi$.
13. *Mackey's Subgroup Theorem*: If H and K are subgroups of G and φ is a character of H, then $(\varphi^G)_K = \sum_{t\in T}(\varphi^t_{H^t\cap K})^K$, where T is a set of representatives for the (H,K)-double cosets in G (so that $G = \dot{\bigcup}_{t\in T} HtK$, a disjoint union).
14. If φ is a character of a normal subgroup N of G, then for each $s \in G$, the conjugate φ^s is a character of N. Moreover, $\varphi^s(n) = \varphi(sns^{-1})$ $(n \in N)$.
15. *Clifford's Theorem*: Let N be a normal subgroup of G, let χ be an irreducible character of G, and let φ be an irreducible constituent of χ_N. Then $\chi_N = m\sum_{i=1}^h \varphi_i$, where $\varphi_1, \dots, \varphi_h$ are the distinct conjugates of φ under the action of G and $m = (\chi_N, \varphi)_N$.

Examples:

1. Given a subgroup H of G, the induced character $(1_H)^G$ equals the permutation character corresponding to the action of G on the set of left cosets of H in G given by $s(tH) = (st)H$ $(s, t \in G)$.
2. The induced character $(1_{\{e\}})^G$ equals the permutation character corresponding to the action of G on itself given by left multiplication. It is the character of the (left) regular representation of G. This character satisfies

$$(1_{\{e\}})^G(s) = \begin{cases} |G| & \text{if } s = e \\ 0 & \text{if } s \neq e. \end{cases}$$

3. As an illustration of Frobenius Reciprocity (Fact 11), we have $((1_{\{e\}})^G, \chi)_G = (1_{\{e\}}, \chi_{\{e\}})_{\{e\}} = \chi(e)$ for any irreducible character χ of G. Hence, $(1_{\{e\}})^G = \sum_{\chi\in Irr(G)} \chi(e)\chi$ (cf. Fact 85.4.8), that is, in the character of the regular representation (see Example 2), each irreducible character appears as a constituent with multiplicity equal to its degree.

85.6 Representations of the Symmetric Group

Definitions:

Given a natural number n, a tuple $\alpha = [\alpha_1, \dots, \alpha_h]$ of nonnegative integers is a (**proper**) **partition** of n (written $\alpha \vdash n$) provided

- $\alpha_i \geq \alpha_{i+1}$ for all $1 \leq i < h$,
- $\sum_{i=1}^h \alpha_i = n$.

The **conjugate partition** of a partition $\alpha \vdash n$ is the partition $\alpha' \vdash n$ with ith component α'_i equal to the number of indices j for which $\alpha_j \geq i$. This partition is also called the **partition associated with** α.

Given two partitions $\alpha = [\alpha_1, \dots, \alpha_h]$ and $\beta = [\beta_1, \dots, \beta_k]$ of n, α **majorizes** (or **dominates**) β if

$$\sum_{i=1}^j \alpha_i \geq \sum_{i=1}^j \beta_i$$

for each $1 \leq j \leq h$. This is expressed by writing $\alpha \succeq \beta$ (or $\beta \preceq \alpha$).

The **Young subgroup** of the symmetric group S_n corresponding to a partition $\alpha = [\alpha_1, \ldots, \alpha_h]$ of n is the internal direct product $S_\alpha = S_{A_1} \times \cdots \times S_{A_h}$, where S_{A_i} is the subgroup of S_n consisting of those permutations that fix every integer *not* in the set

$$A_i = \left\{ 1 \leq k \leq n \;\middle|\; \sum_{j=1}^{i-1} \alpha_j < k \leq \sum_{j=1}^{i} \alpha_j \right\}$$

(an empty sum being interpreted as zero).

The **alternating character** of the symmetric group S_n is the character ϵ_n given by

$$\epsilon_n(\sigma) = \begin{cases} 1 & \text{if } \sigma \text{ is even,} \\ -1 & \text{if } \sigma \text{ is odd.} \end{cases}$$

Let G be a subgroup of S_n and let χ be a character of G. The **generalized matrix function** $d_\chi : \mathbb{C}^{n\times n} \to \mathbb{C}$ is defined by

$$d_\chi(A) = \sum_{s\in G} \chi(s) \prod_{j=1}^{n} a_{js(j)}.$$

When $G = S_n$ and χ is irreducible, d_χ is called an **immanant**.

Facts:

The following facts can be found in [JK81, pp. 15, 35–37] or [Mer97, pp. 99–103, 214].

1. If χ is a character of the symmetric group S_n, then $\chi(\sigma)$ is an integer for each $\sigma \in S_n$.
2. *Irreducible character associated with a partition*: Given a partition α of n, there is a unique irreducible character χ_α that is a constituent of both the induced character $(1_{S_\alpha})^{S_n}$ and the induced character $((\epsilon_n)_{S_{\alpha'}})^{S_n}$. The map $\alpha \mapsto \chi_\alpha$ defines a bijection from the set of partitions of n to the set $Irr(S_n)$ of irreducible characters of S_n.
3. If α and β are partitions of n, then the irreducible character χ_α is a constituent of the induced character $(1_{S_\beta})^{S_n}$ if and only if α majorizes β.
4. If α is a partition of n, then $\chi_{\alpha'} = \epsilon_n \chi_\alpha$.
5. *Schur's inequality*: Let χ be an irreducible character of a subgroup G of S_n. For any positive semidefinite matrix $A \in \mathbb{C}^{n\times n}$, $d_\chi(A)/\chi(e) \geq \det A$.

Conjectures and Open Questions:

1. *Permanental Dominance* (or *Permanent-on-Top*) *Conjecture*: Let χ be an irreducible character of a subgroup G of S_n. For any positive semidefinite matrix $A \in \mathbb{C}^{n\times n}$, $\operatorname{per} A \geq d_\chi(A)/\chi(e)$ (cf. Fact 5 and Examples 6 and 7).

Examples:

1. $\alpha = [5, 3^2, 2, 1^3]$ (meaning $[5, 3, 3, 2, 1, 1, 1]$) is a partition of 16. Its conjugate is $\alpha' = [7, 4, 3, 1, 1]$.
2. $\chi_{[n]} = 1_{S_n}$ and $\chi_{[1^n]} = \epsilon_n$.
3. In the notation of Example 85.4.3, we have $\chi_0 = \chi_{[4]}$, $\chi_1 = \chi_{[1^4]}$, $\chi_2 = \chi_{[2^2]}$, $\chi_3 = \chi_{[3,1]}$, and $\chi_4 = \chi_{[2,1^2]}$.
4. According to Fact 4, a partition α of n is self-conjugate (meaning $\alpha' = \alpha$) if and only if $\chi_\alpha(\sigma) = 0$ for every odd permutation $\sigma \in S_n$.
5. As an illustration of Fact 3, we have

$$\left(1_{S_{[2,1^2]}}\right)^{S_4} = \chi_{[4]} + \chi_{[3,1]} + \chi_{[3,1]} + \chi_{[2^2]} + \chi_{[2,1^2]}.$$

The irreducible constituents of the induced character $(1_{S_{[2,1^2]}})^{S_4}$ are the terms on the right-hand side of the equation. Note that $[4]$, $[3,1]$, $[2^2]$, and $[2,1^2]$ are precisely the partitions of 4 that majorize $[2,1^2]$ in accordance with the fact.

6. When $G = S_n$ and $\chi = \epsilon_n$ (the alternating character), $d_\chi(A)$ is the determinant of $A \in \mathbb{C}^{n\times n}$.
7. When $G = S_n$ and $\chi = 1_G$ (the principal character), $d_\chi(A) = \sum_{s\in G}\prod_{j=1}^{n} a_{js(j)}$ is called the *permanent* of $A \in \mathbb{C}^{n\times n}$, denoted *per* A. See Chapter 43.

One of the earliest surveys on nonassociative algebras is the article by Shirshov [Shi58] that introduced the phrase "rings that are nearly associative." The first book in the English language devoted to a systematic study of nonassociative algebras is Schafer [Sch66]. A comprehensive exposition of the work of the Russian school is Zhevlakov, Slinko, Shestakov, and Shirshov [ZSS82]. A collection of open research problems in algebra, including many problems on nonassociative algebra, is the *Dniester Notebook* [FKS93]; the survey article by Kuzmin and Shestakov [KS95] is from the same period. Three books on Jordan algebras that contain substantial material on general nonassociative algebras are Braun and Koecher [BK66], Jacobson [Jac68], and McCrimmon [McC04]. Recent research appears in the *Proceedings of the International Conferences on Nonassociative Algebra and Its Applications* [Gon94], [CGG00], [SSS06]. The present chapter provides very limited information on Lie algebras, since they are the subject of Chapter 87. The last section (Section 86.9) presents three applications of computational linear algebra to the study of polynomial identities for nonassociative algebras: Pseudorandom vectors in a nonassociative algebra, the expansion matrix for a nonassociative operation, and the representation theory of the symmetric group.

86.1 Introduction

Definitions:

An **algebra** is a vector space A over a field F together with a bilinear **multiplication** $(x, y) \mapsto xy$ from $A \times A$ to A; that is, **distributivity** holds for all $a, b \in F$ and all $x, y, z \in A$:

$$(ax + by)z = a(xz) + b(yz), \qquad x(ay + bz) = a(xy) + b(xz).$$

The **dimension** of an algebra A is its dimension as a vector space.

An algebra A is **finite dimensional** if A is a finite dimensional vector space.

The **structure constants** of a finite dimensional algebra A over F with basis $\{x_1, \ldots, x_n\}$ are the scalars $c_{ij}^k \in F$ $(i, j, k = 1, \ldots, n)$ defined by:

$$x_i x_j = \sum_{k=1}^{n} c_{ij}^k x_k.$$

An algebra A is **unital** if there exists an element $1 \in A$ for which

$$1x = x1 = x \quad \text{for all } x \in A.$$

An **involution** of the algebra A is a linear mapping $j\colon A \to A$ satisfying

$$j(j(x)) = x \quad \text{and} \quad j(xy) = j(y)j(x) \qquad \text{for all } x, y \in A.$$

An algebra A is a **division algebra** if for every $x, y \in A$ with $x \neq 0$ the equations $xv = y$ and $wx = y$ are solvable in A.

The **associator** in an algebra is the trilinear function

$$(x, y, z) = (xy)z - x(yz).$$

An algebra A is **associative** if the associator vanishes identically:

$$(x, y, z) = 0 \quad \text{for all } x, y, z \in A.$$

An algebra is **nonassociative** if the above identity is not necessarily satisfied.

An algebra A is **alternative** if it satisfies the **right and left alternative identities**

$$(y, x, x) = 0 \quad \text{and} \quad (x, x, y) = 0 \qquad \text{for all } x, y \in A.$$

An algebra A is **anticommutative** if it satisfies the identity

$$x^2 = 0 \quad \text{for all } x \in A.$$

(This implies that $xy = -yx$, and the converse holds in characteristic $\neq 2$.)

The **Jacobian** in an anticommutative algebra is defined by

$$J(x, y, z) = (xy)z + (yz)x + (zx)y.$$

A **Lie algebra** is an anticommutative algebra satisfying the **Jacobi identity**

$$J(x, y, z) = 0 \quad \text{for all } x, y, z \in A.$$

A **Malcev algebra** is an anticommutative algebra satisfying the identity

$$J(x, y, xz) = J(x, y, z)x \quad \text{for all } x, y, z \in A.$$

The **commutator** in an algebra A is the bilinear function

$$[x, y] = xy - yx.$$

The **minus algebra** A^- of an algebra A is the algebra with the same underlying vector space as A but with $[x, y]$ as the multiplication.

An algebra A is **commutative** if it satisfies the identity

$$xy = yx \quad \text{for all } x, y \in A.$$

A **Jordan algebra** is a commutative algebra satisfying the **Jordan identity**

$$(x^2, y, x) = 0 \quad \text{for all } x, y \in A.$$

The **Jordan product** (or **anticommutator**) in an algebra A is the bilinear function

$$x * y = xy + yx.$$

(The notation $x \circ y$ is also common.)

The **plus algebra** A^+ of an algebra A over a field F of characteristic $\neq 2$ is the algebra with the same underlying vector space as A but with $x \cdot y = \frac{1}{2}(x * y)$ as the multiplication.

A Jordan algebra is called **special** if it is isomorphic to a subalgebra of A^+ for some associative algebra A; otherwise, it is called **exceptional**.

Given two algebras A and B over a field F, a **homomorphism** from A to B is a linear mapping $f\colon A \to B$ that satisfies $f(xy) = f(x)f(y)$ for all $x, y \in A$.

An **isomorphism** is a homomorphism that is a linear isomorphism of vector spaces.

Let A be an algebra. Given two subsets $B, C \subseteq A$ we write BC for the **subspace spanned by the products** yz where $y \in B$, $z \in C$.

A **subalgebra** of A is a subspace B satisfying $BB \subseteq B$.

The **subalgebra generated by a set** $S \subseteq A$ is the smallest subalgebra of A containing S.

A (two-sided) **ideal** of an algebra A is a subalgebra B satisfying $AB + BA \subseteq B$.

Given two algebras A and B over the field F, the **(external) direct sum** of A and B is the vector space direct sum $A \oplus B$ with the multiplication

$$(w, x)(y, z) = (wy, xz) \quad \text{for all } w, y \in A \quad \text{ and all } x, z \in B.$$

Given an algebra A with two ideals B and C, we say that A is the **(internal) direct sum** of B and C if $A = B \oplus C$ (direct sum of subspaces).

Facts: [Shi58], [Sch66], [ZSS82], [KS95]

1. Every finite dimensional associative algebra over a field F is isomorphic to a subalgebra of a matrix algebra $F^{n \times n}$ for some n.
2. The algebra A^- is always anticommutative. If A is associative, then A^- is a Lie algebra.
3. (Poincaré–Birkhoff–Witt Theorem or PBW Theorem) Every Lie algebra is isomorphic to a subalgebra of A^- for some associative algebra A.
4. The algebra A^+ is always commutative. If A is associative, then A^+ is a Jordan algebra. (See Example 86.9.2.) If A is alternative, then A^+ is a Jordan algebra.
5. The analogue of the PBW theorem for Jordan algebras is false: Not every Jordan algebra is special. (See Example 4.)
6. Every associative algebra is alternative.
7. (Artin's Theorem) An algebra is alternative if and only if every subalgebra generated by two elements is associative.
8. Every Lie algebra is a Malcev algebra.
9. Every Malcev algebra generated by two elements is a Lie algebra.
10. If A is an alternative algebra, then A^- is a Malcev algebra. (See Example 86.9.3.)
11. In an external direct sum of algebras, the summands are ideals.

Examples:

1. Associativity is satisfied when the elements of the algebra are mappings of a set into itself with the composition of mappings taken as multiplication. Such is the multiplication in the algebra $\operatorname{End} V$, the algebra of linear operators on the vector space V. Every associative algebra is isomorphic to a subalgebra of the algebra $\operatorname{End} V$, for some V. Thus, the condition of associativity of multiplication characterizes the *algebras of linear operators.* (Note that $\operatorname{End} V$ is also denoted $L(V, V)$ elsewhere in this book, but $\operatorname{End} V$ is the standard notation in the study of algebras.)

2. *Cayley–Dickson doubling process.* Let A be a unital algebra over F with an involution $x \mapsto \overline{x}$ satisfying

$$x + \overline{x},\ x\,\overline{x} \in F \quad \text{for all } x \in A. \tag{86.1}$$

   Let $a \in F$, $a \neq 0$. The algebra (A, a) is defined as follows: The underlying vector space is $A \oplus A$, addition and scalar multiplication are defined by the vector space formulas

$$(x_1, x_2) + (y_1, y_2) = (x_1 + y_1, x_2 + y_2), \quad c(x_1, x_2) = (cx_1, cx_2) \qquad \text{for all } c \in F, \tag{86.2}$$

   and multiplication is defined by the formula

$$(x_1, x_2)(y_1, y_2) = (\, x_1 y_1 + a y_2 \overline{x_2},\ \overline{x_1} y_2 + y_1 x_2 \,). \tag{86.3}$$

   This algebra has an involution defined by

$$\overline{(x_1, x_2)} = (\overline{x_1}, -x_2). \tag{86.4}$$

   In particular, starting with a field F of characteristic $\neq 2$, we obtain the following examples:

   (a) The algebra $\mathbb{C}(a) = (F, a)$ is commutative and associative. If the polynomial $x^2 + a$ is irreducible over F, then $\mathbb{C}(a)$ is a field; otherwise, $\mathbb{C}(a) \cong F \oplus F$ (algebra direct sum).

   (b) The algebra $\mathbb{H}(a, b) = (\mathbb{C}(a), b)$ is an algebra of *generalized quaternions*, which is associative but not commutative.

   (c) The algebra $\mathbb{O}(a, b, c) = (\mathbb{H}(a, b), c)$ is an algebra of *generalized octonions* or a *Cayley–Dickson algebra*, which is alternative but not associative. (See Example 86.9.1.)

   The algebras of generalized quaternions and octonions may also be defined over a field of characteristic 2 (see [Sch66], [ZSS82]).

3. *Real division algebras* [EHH91, Part B]. In the previous example, taking F to be the field $\mathbb{R}$ of real numbers and $a = b = c = -1$, we obtain the field $\mathbb{C}$ of *complex numbers*, the associative division algebra $\mathbb{H}$ of *quaternions*, and the alternative division algebra $\mathbb{O}$ of *octonions* (also known as the *Cayley numbers*). Real division algebras exist only in dimensions 1, 2, 4, and 8, but there are many other examples: The algebras $\mathbb{C}$, $\mathbb{H}$, and $\mathbb{O}$ with the multiplication $x \cdot y = \overline{x}\,\overline{y}$ are still division algebras, but they are not alternative and they are not unital.
4. *The Albert algebra.* Let $\mathbb{O}$ be the octonions and let $M_3(\mathbb{O})$ be the algebra of 3×3 matrices over $\mathbb{O}$ with involution induced by the involution of $\mathbb{O}$; that is, $(a_{ij}) \mapsto (\overline{a_{ji}})$. The subalgebra $H_3(\mathbb{O})$ of Hermitian matrices in $M_3(\mathbb{O})^+$ is an exceptional Jordan algebra, the Albert algebra: There is no associative algebra A such that $H_3(\mathbb{O})$ is isomorphic to a subalgebra of A^+.

86.2 General Properties

Definitions:

Given an algebra A and an ideal I, the **quotient algebra** A/I is the quotient space A/I with multiplication defined by $(x + I)(y + I) = xy + I$ for all $x, y \in A$.

The algebra A is **simple** if $AA \neq \{0\}$ and A has no ideals apart from $\{0\}$ and A.

The algebra A is **semisimple** if it is the direct sum of simple algebras. (The definition of semisimple that is used in the theory of Lie algebras is different; see Chapter 87.)

Set $A^1 = A^{(1)} = A$, and then by induction define

$$A^{n+1} = \sum_{i+j=n+1} A^i A^j \quad \text{and} \quad A^{(n+1)} = A^{(n)} A^{(n)} \qquad \text{for } n \geq 1.$$

The algebra A is **nilpotent** if $A^n = \{0\}$ for some n and **solvable** if $A^{(s)} = \{0\}$ for some s. The smallest natural number n (respectively, s) with this property is the **nilpotency index** (respectively, **solvability index**) of A.

An element $x \in A$ is **nilpotent** if the subalgebra it generates is nilpotent.

A **nil algebra** (respectively, **nil ideal**) is an algebra (respectively, ideal) in which every element is nilpotent.

An algebra is **power associative** if every element generates an associative subalgebra.

An **idempotent** is an element $e \neq 0$ of an algebra A satisfying $e^2 = e$. Two idempotents e, f are **orthogonal** if $ef = fe = 0$.

For an algebra A over a field F, the **degree** of A is defined to be the maximal number of mutually orthogonal idempotents in the scalar extension $\overline{F} \otimes_F A$, where $\overline{F}$ is the algebraic closure of F.

The **associator ideal** $D(A)$ of the algebra A is the ideal generated by all the associators. The **associative center** or **nucleus** $N(A)$ of A is defined by

$$N(A) = \{\, x \in A \mid (x, A, A) = (A, x, A) = (A, A, x) = \{0\} \,\}.$$

The **center** $Z(A)$ of the algebra A is defined by

$$Z(A) = \{\, x \in N(A) \mid [x, A] = \{0\} \,\}.$$

The **right and left multiplication operators** by an element $x \in A$ are defined by

$$R_x \colon y \mapsto yx, \qquad L_x \colon y \mapsto xy.$$

The **multiplication algebra** of the algebra A is the subalgebra $M(A)$ of the associative algebra $\operatorname{End} A$ (of endomorphisms of the vector space A) generated by all R_x and L_x for $x \in A$.

The **right multiplication algebra** of the algebra A is the subalgebra $R(A)$ of $\operatorname{End} A$ generated by all R_x for $x \in A$.

The **centroid** $C(A)$ of the algebra A is the centralizer of the multiplication algebra $M(A)$ in the algebra $\operatorname{End} A$; that is,

$$C(A) = \{\, T \in \operatorname{End} A \mid TR_x = R_x T = R_{Tx}, \quad TL_x = L_x T = L_{Tx}, \qquad \text{for any } x \in A \,\}.$$

An algebra A over a field F is **central** if $C(A) = F$.

The **unital hull** $A^\sharp$ of an algebra A over a field F is defined as follows: If A is unital, then $A^\sharp = A$; and when A has no unit, we set $A^\sharp = A \oplus F$ (vector space direct sum) and define multiplication by assuming that A is a subalgebra and the unit of F is the unit of $A^\sharp$.

Let $\mathcal{M}$ be a class of algebras closed under homomorphic images. A subclass $\mathcal{R}$ of $\mathcal{M}$ is said to be **radical** if

1. $\mathcal{R}$ is closed under homomorphic images.
2. For each $A \in \mathcal{M}$ there is an ideal $\mathcal{R}(A)$ of A such that $\mathcal{R}(A) \in \mathcal{R}$ and $\mathcal{R}(A)$ contains every ideal of A contained in $\mathcal{R}$.
3. $\mathcal{R}(A/\mathcal{R}(A)) = \{0\}$.

In this case, we call the ideal $\mathcal{R}(A)$ the $\mathcal{R}$-**radical** of A. The algebra A is said to be $\mathcal{R}$-**semisimple** if $\mathcal{R}(A) = \{0\}$.

If the subclass *Nil* of nil-algebras is radical in the class $\mathcal{M}$, then the corresponding ideal $\operatorname{Nil} A$, for $A \in \mathcal{M}$, is called the **nil radical** of A. In this case, the algebra A is called **nil-semisimple** if $\operatorname{Nil} A = \{0\}$. By definition, $\operatorname{Nil} A$ contains all two-sided nil-ideals of A, and the quotient algebra $A/\operatorname{Nil} A$ is nil-semisimple, that is, $\operatorname{Nil}(A/\operatorname{Nil} A) = \{0\}$.

If the subclass *Nilp* of nilpotent algebras (or the subclass *Solv* of solvable algebras) is radical in the class $\mathcal{M}$, then the corresponding ideal $\operatorname{Nilp} A$ (respectively, $\operatorname{Solv} A$), for $A \in \mathcal{M}$, is called the **nilpotent radical** (respectively, the **solvable radical**) of A.

For an algebra A over F, an A-**bimodule** is a vector space M over F with bilinear mappings

$$A \times M \to M,\ (x, m) \mapsto xm \quad \text{and} \quad M \times A \to M,\ (m, x) \mapsto mx.$$

The **split null extension** $E(A, M)$ of A by M is the algebra over F with underlying vector space $A \oplus M$ and multiplication

$$(x + m)(y + n) = xy + (xn + my) \quad \text{for all } x, y \in A,\ m, n \in M.$$

For an algebra A, the **regular bimodule** $\operatorname{Reg}(A)$ is the underlying vector space of A considered as an A-bimodule, interpreting mx and xm as multiplication in A.

If M is an A-bimodule, then the mappings

$$\rho(x) \colon m \mapsto mx, \qquad \lambda(x) \colon m \mapsto xm,$$

are linear operators on M, and the mappings

$$x \mapsto \rho(x), \qquad x \mapsto \lambda(x),$$

are linear mappings from A to the algebra $\operatorname{End}_F M$. The pair (λ, ρ) is called the **birepresentation** of A associated with the bimodule M.

The notions of **sub-bimodule, homomorphism of bimodules**, **irreducible bimodule**, and **faithful birepresentation** are defined in the natural way. The sub-bimodules of a regular A-bimodule are exactly the two-sided ideals of A.

Facts: [Sch66], [Jac68], [ZSS82]

1. If A is a simple algebra, then $AA = A$.
2. (Isomorphism theorems)
   - (a) If $f \colon A \to B$ is a homomorphism of algebras over the field F, then $A/\ker(F) \cong \operatorname{im}(f) \subseteq B$.
   - (b) If B_1 and B_2 are ideals of the algebra A with $B_2 \subseteq B_1$, then $(A/B_2)/(B_1/B_2) \cong A/B_1$.
   - (c) If S is a subalgebra of A and B is an ideal of A, then $B \cap S$ is an ideal of S and $(B + S)/\, B \cong S/(B \cap S)$.
3. The algebra A is nilpotent of index n if and only if any product of n elements (with any arrangement of parentheses) equals zero, and if there exists a nonzero product of $n - 1$ elements.
4. Every nilpotent algebra is solvable; the converse is not generally true. (See Example 1.)
5. In any algebra A, the sum of two solvable ideals is again a solvable ideal. If A is finite-dimensional, then A contains a unique maximal solvable ideal $\operatorname{Solv} A$, and the quotient algebra $A/\operatorname{Solv} A$ does not contain nonzero solvable ideals. In other words, the subclass *Solv* of solvable algebras is radical in the class of all finite dimensional algebras.
6. An algebra A is associative if and only if $D(A) = \{0\}$, if and only if $N(A) = A$.

7. Every solvable associative algebra is nilpotent.
8. The subclass *Nilp* of nilpotent algebras is radical in the class of all finite dimensional associative algebras.
9. A finite dimensional associative algebra A is semisimple if and only if $\operatorname{Nilp} A = \{0\}$.
10. The previous two facts imply that every finite dimensional associative algebra A contains a unique maximal nilpotent ideal N such that the quotient algebra A/N is isomorphic to a direct sum of simple algebras.
11. Over an algebraically closed field F, every finite dimensional simple associative algebra is isomorphic to the algebra $F^{n\times n}$ of $n \times n$ matrices over F, for some $n \geq 1$.
12. The subclass *Nilp* is not radical in the class of finite dimensional Lie algebras. (See Example 1.)
13. Over a field of characteristic zero, an algebra is power associative if and only if

$$x^2x = xx^2 \quad \text{and} \quad (x^2x)x = x^2x^2 \qquad \text{for all } x.$$

14. Every power associative algebra A contains a unique maximal nil ideal $\operatorname{Nil} A$, and the quotient algebra $A/\operatorname{Nil} A$ is nil-semisimple; that is, it does not contain nonzero nil ideals. In other words, the subclass *Nil* of nil-algebras is radical in the class of all power associative algebras.
15. For a finite dimensional alternative or Jordan algebra A we have $\operatorname{Nil} A = \operatorname{Solv} A$.
16. For finite dimensional commutative power associative algebras, the question of the equality of the nil and solvable radicals is still open, and is known as *Albert's problem.* An equivalent question is: Are there any simple finite dimensional commutative power associative nil algebras?
17. Every nil-semisimple finite dimensional commutative power associative algebra over a field of characteristic $\neq 2, 3, 5$ has a unit element and decomposes into a direct sum of simple algebras. Every such simple algebra is either a Jordan algebra or a certain algebra of degree 2 over a field of positive characteristic.
18. Direct expansion shows that these two identities are valid in every algebra:

$$\begin{aligned} x(y,z,w) + (x,y,z)w &= (xy,z,w) - (x,yz,w) + (x,y,zw), \\ [xy,z] - x[y,z] - [x,z]y &= (x,y,z) - (x,z,y) + (z,x,y). \end{aligned}$$

From these it follows that the associative center and the center are subalgebras, and

$$D(A) = (A,A,A) + (A,A,A)A = (A,A,A) + A(A,A,A).$$

19. If $z \in Z(A)$, then for any $x \in A$ we have

$$R_zR_x = R_xR_z = R_{zx} = R_{xz}.$$

20. If A is unital, then its centroid $C(A)$ is isomorphic to its center $Z(A)$. If A is simple, then $C(A)$ is a field that contains the base field F.
21. Let A be a finite dimensional algebra with multiplication algebra $M(A)$. Then
    (a) A is nilpotent if and only if $M(A)$ is nilpotent.
    (b) If A is semisimple, then so is $M(A)$.
    (c) If A is simple, then so is $M(A)$, and $M(A) \cong \operatorname{End}_{C(A)} A$.
22. An algebra A is simple if and only if the bimodule $\operatorname{Reg}(A)$ is irreducible.
23. If A is an alternative algebra (respectively, a Jordan algebra), then its unital hull $A^\sharp$ is also alternative (respectively, Jordan).

Examples:

1. Let A be algebra with basis x, y, and multiplication given by $x^2 = y^2 = 0$ and $xy = -yx = y$. Then A is a Lie algebra and $A^{(2)} = \{0\}$ but $A^n \neq \{0\}$ for any $n \geq 1$. Thus, A is solvable but not nilpotent.
2. Let A be an algebra over a field F with basis x_1, x_2, y, z and the following nonzero products of basis elements:
$$yx_1 = ax_1y = x_2, \quad zx_2 = ax_2z = x_1,$$
where $0 \neq a \in F$. Then $I_1 = Fx_1 + Fx_2 + Fy$ and $I_2 = Fx_1 + Fx_2 + Fz$ are different maximal nilpotent ideals in A. By choosing $a = 1$ or $a = -1$ we obtain a commutative or anticommutative algebra A.
3. In general, in a nonassociative algebra, a power of an element is not uniquely determined. In the previous example, for the element $w = x_1 + x_2 + y + z$ we have
$$w^2w^2 = 0 \quad \text{but} \quad w(ww^2) = (1+a)(x_1 + x_2).$$
4. Let $A_1, \ldots, A_n$ be simple algebras over a field F with bases
$$\{v_i^1 \,|\, i \in I_1\}, \ \ldots, \ \{v_i^n \,|\, i \in I_n\}.$$
Consider the algebra $A = Fe \oplus A_1 \oplus \cdots \oplus A_n$ (vector space direct sum) with multiplication defined by the following conditions:
   (a) The A_i are subalgebras of A.
   (b) $A_iA_j = \{0\}$ for $i \neq j$.
   (c) $ev_i^j = v_i^je = e$ for all i, j.
   (d) $e^2 = e$.

   Then $I = Fe$ is the unique minimal ideal in A, and $I^2 = I$. In particular, $\operatorname{Solv} A = \{0\}$, but A is not semisimple (compare with the Lie algebra case).
5. *Suttles' example* [Sut72]. Let A be a commutative algebra over a field F of characteristic $\neq 2$, with basis x_i $(1 \leq i \leq 5)$ and the following multiplication table (all other products are zero):
$$x_1x_2 = x_2x_4 = -x_1x_5 = x_3, \quad x_1x_3 = x_4, \quad x_2x_3 = x_5.$$
Then A is a solvable power associative nil algebra that is not nilpotent. Moreover, Nil A = Solv $A = A$, and Nilp A does not exist (if F is infinite, then A has infinitely many maximal nilpotent ideals).

86.3 Composition Algebras

Definitions:

A **composition algebra** is an algebra A with unit 1 over a field F of characteristic $\neq 2$ together with a **norm** $n(x)$ (a nondegenerate quadratic form on the vector space A) that **admits composition** in the sense that
$$n(xy) = n(x)n(y) \quad \text{for all } x \in A.$$

A **quadratic algebra** A over a field F is a unital algebra in which every $x \in A$ satisfies the condition $x^2 \in \operatorname{Span}(x, 1)$. In other words, every subalgebra of A generated by a single element has dimension ≤ 2.

A composition algebra A is **split** if it contains zero-divisors, that is, if $xy = 0$ for some nonzero $x, y \in A$.

Facts: [Sch66], [Jac68], [ZSS82], [Bae02]

1. Every composition algebra A is alternative and quadratic. Moreover, every element $x \in A$ satisfies the equation
$$x^2 - t(x)x + n(x) = 0,$$
where $t(x)$ is a linear form on A (the *trace*) and $n(x)$ is the original quadratic form on A (the norm).
2. For a composition algebra A the following conditions are equivalent:
   (a) A is split;
   (b) $n(x) = 0$ for some nonzero $x \in A$;
   (c) A contains an idempotent $e \neq 1$.
3. Let A be a unital algebra over a field F with an involution $x \mapsto \overline{x}$ satisfying Eq. (86.1) from Example 86.1.2. The Cayley–Dickson doubling process gives the algebra (A, a) defined by Eqs. (86.2) to (86.4). It is clear that A is isomorphically embedded into (A, a) and that $\dim(A, a) = 2 \dim A$. For $v = (0, 1)$, we have $v^2 = a$ and $(A, a) = A \oplus Av$. For any $y = y_1 + y_2 v \in (A, a)$, we have $\overline{y} = \overline{y_1} - y_2 v$.
4. In a composition algebra A, the mapping $x \mapsto \overline{x} = t(x) - x$ is an involution of A fixing the elements of the field $F = F1$. Conversely, if A is an alternative algebra with unit 1 and involution $x \mapsto \overline{x}$ satisfying Eq. (86.1) from Example 86.1.2, then $x\,\overline{x} \in F$ and the quadratic form $n(x) = x\,\overline{x}$ satisfies $n(xy) = n(x)n(y)$.
5. The mapping $y \mapsto \overline{y}$ is an involution of (A, a) extending the involution $x \mapsto \overline{x}$ of A. Moreover, $y + \overline{y}$ and $y\,\overline{y}$ are in F for every $y \in (A, a)$. If the quadratic form $n(x) = x\,\overline{x}$ is nondegenerate on A, then the quadratic form $n(y) = y\,\overline{y}$ is nondegenerate on (A, a), and the form $n(y)$ admits composition on (A, a) if and only if A is associative.
6. Every composition algebra over a field F of characteristic $\neq 2$ is isomorphic to F or to one of the algebras of types 2a–2c obtained from F by the Cayley–Dickson process as in Example 86.1.2.
7. Every split composition algebra over a field F is isomorphic to one of the algebras $F \oplus F$, $M_2(F)$, $\mathrm{Zorn}(F)$ described in Examples 2 to 4 below.
8. Every finite dimensional composition algebra without zero divisors is a division algebra, and so every composition algebra is either split or a division algebra.
9. Every composition algebra of dimension > 1 over an algebraically closed field is split, and so every composition algebra over an algebraically closed field F is isomorphic to one of the algebras F, $F \oplus F$, $M_2(F)$, $\mathrm{Zorn}(F)$.

Examples:

1. The fields of real numbers $\mathbb{R}$ and complex numbers $\mathbb{C}$, the quaternions $\mathbb{H}$, and the octonions $\mathbb{O}$, are real composition algebras with the Euclidean norm $n(x) = x\overline{x}$. The first three are associative; the algebra $\mathbb{O}$ provides us with the first and most important example of a nonassociative alternative algebra.
2. Let F be a field and let $A = F \oplus F$ be the direct sum of two copies of the field with the exchange involution $\overline{(a, b)} = (b, a)$, the trace $t((a, b)) = a + b$, and the norm $n((a, b)) = ab$. Then A is a two-dimensional split composition algebra.

3. Let $A = M_2(F)$ be the algebra of 2×2 matrices over F with the symplectic involution
$$x = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \longmapsto \overline{x} = \begin{bmatrix} d & -b \\ -c & a \end{bmatrix},$$
the matrix trace $t(x) = a + d$, and the determinant norm $n(x) = ad - bc$. Then A is a 4-dimensional split composition algebra.
4. An eight-dimensional split composition algebra is the *Zorn vector-matrix algebra* (or the *Cayley–Dickson matrix algebra*), obtained by taking $A = \text{Zorn}(F)$, which consists of all 2×2 block matrices with scalars on the diagonal and 3×1 column vectors off the diagonal
$$\text{Zorn}(F) = \left\{ x = \begin{bmatrix} a & \mathbf{u} \\ \mathbf{v} & b \end{bmatrix} \;\middle|\; a, b \in F,\ \mathbf{u}, \mathbf{v} \in F^3 \right\},$$
with norm, involution, and product
$$n(x) \quad = ab - (\mathbf{u}, \mathbf{v}), \qquad \overline{x} = \begin{bmatrix} b & -\mathbf{u} \\ -\mathbf{v} & a \end{bmatrix},$$
$$x_1x_2 = \begin{bmatrix} a_1a_2 + (\mathbf{u}_1, \mathbf{v}_2) & a_1\mathbf{u}_2 + \mathbf{u}_1b_2 - \mathbf{v}_1 \times \mathbf{v}_2 \\ \mathbf{v}_1a_2 + b_1\mathbf{v}_2 + \mathbf{u}_1 \times \mathbf{u}_2 & b_1b_2 + (\mathbf{v}_1, \mathbf{u}_2) \end{bmatrix};$$
the scalar and vector products are defined for $\mathbf{u} = [u_1, u_2, u_3]^T$ and $\mathbf{v} = [v_1, v_2, v_3]^T$ by
$$(\mathbf{u}, \mathbf{v}) = u_1v_1 + u_2v_2 + u_3v_3, \qquad \mathbf{u} \times \mathbf{v} = [u_2v_3 - u_3v_2, u_3v_1 - u_1v_3, u_1v_2 - u_2v_1].$$

Applications:

1. If we write the equation $n(x)n(y) = n(xy)$ in terms of the coefficients of the algebra elements x, y with respect to an orthogonal basis for each of the composition algebras $\mathbb{R}$, $\mathbb{C}$, $\mathbb{H}$, $\mathbb{O}$ given in Example 86.1.3, then we obtain an identity expressing the multiplicativity of a quadratic form:
$$\left(x_1^2 + \cdots + x_k^2\right)\left(y_1^2 + \cdots + y_k^2\right) = z_1^2 + \cdots + z_k^2.$$
Here the z_i are bilinear functions in the x_i and y_i: To be precise, z_i is the coefficient of the ith basis vector in the product of the elements $x = (x_1, \ldots, x_k)$ and $y = (y_1, \ldots, y_k)$. By Hurwitz' theorem, such a *k-square identity* exists only for $k = 1, 2, 4, 8$.

86.4 Alternative Algebras

Definitions:

A **left alternative algebra** is one satisfying the identity $(x, x, y) = 0$.

A **right alternative algebra** is one satisfying the identity $(y, x, x) = 0$.

A **flexible algebra** is one satisfying the identity $(x, y, x) = 0$.

An **alternative algebra** is one satisfying all three identities (any two imply the third).

The **Moufang identities** play an important role in the theory of alternative algebras:

$$(xy \cdot z)y = x(yzy) \qquad \textbf{right Moufang identity}$$
$$(yzy)x = y(z \cdot yx) \qquad \textbf{left Moufang identity}$$
$$(xy)(zx) = x(yz)x \qquad \textbf{central Moufang identity}$$

(The terms yzy and $x(yz)x$ are well defined by the flexible identity.)

An **alternative bimodule** over an alternative algebra A is an A-bimodule M for which the split null extension $E(A, M)$ is alternative.

Let A be an alternative algebra, let M be an alternative A-bimodule, and let (λ, ρ) be the associated birepresentation of A. The algebra A **acts nilpotently** on M if the subalgebra of $\operatorname{End} M$, which is generated by the elements $\lambda(x)$, $\rho(x)$ for all $x \in A$, is nilpotent. If $y \in A$, then y **acts nilpotently** on M if the elements $\lambda(y)$, $\rho(y)$ generate a nilpotent subalgebra of $\operatorname{End} M$.

A finite dimensional alternative algebra A over a field F is **separable** if the algebra $A_K = K \otimes_F A$ is nil-semisimple for any extension K of the field F.

Facts: [Sch66], [ZSS82] Additional facts about alternative algebras are given in Section 86.1 and facts about right alternative algebras are given in Section 86.6:

1. Every commutative or anticommutative algebra is flexible.
2. Substituting $x + z$ for x in the left alternative identity, and using distributivity, we obtain
$$(x, z, y) + (z, x, y) = 0.$$
This is the *linearization on x* of the left alternative identity. Linearizing the right alternative identity in the same way, we get
$$(y, x, z) + (y, z, x) = 0.$$
From the last two identities, it follows that in any alternative algebra A the associator (x, y, z) is a skew-symmetric (alternating) function of the arguments x, y, z.
3. Every alternative algebra is power associative (Corollary of Artin's Theorem, Fact 86.1.7). In particular, the nil radical $\operatorname{Nil} A$ exists in the class of alternative algebras.
4. Every alternative algebra satisfies the three Moufang identities and the identities
$$(x, y, yz) = (x, y, z)y, \qquad (x, y, zy) = y(x, y, z).$$
5. A bimodule M over an alternative algebra A is alternative if and only if the following relations hold in the split null extension $E(A, M)$:
$$(x, m, x) = 0 \quad \text{and} \quad (x, m, y) = (m, y, x) = (y, x, m) \ \text{ for all } x, y \in A \quad \text{and} \quad m \in M.$$
6. It follows from the definition of alternative bimodule and the Moufang identities that
$$[\rho(x), \lambda(x)] = 0, \qquad \rho(x^k) = (\rho(x))^k \quad \text{for } k \geq 1, \qquad \lambda(x^k) = (\lambda(x))^k \quad \text{for } k \geq 1.$$
This implies that any nilpotent element of an alternative algebra acts nilpotently on any bimodule.
7. If every element of an alternative algebra A acts nilpotently on a finite dimensional alternative A-bimodule M, then A acts nilpotently on M.
8. A nilpotent algebra A acts nilpotently on the A-bimodule M if and only if the algebra $E(A, M)$ is nilpotent.
9. In a finite dimensional alternative algebra A, every nil subalgebra is nilpotent. In particular, the nil radical $\operatorname{Nil} A$ is nilpotent.
10. The subclass *Nilp* of nilpotent algebras is radical in the class of all finite dimensional alternative algebras. For any finite dimensional alternative algebra A, we have
$$\operatorname{Nil} A = \operatorname{Solv} A = \operatorname{Nilp} A.$$
11. Let A be a finite dimensional alternative algebra. The quotient algebra $A/\operatorname{Nil} A$ is semisimple; that is, it decomposes into a direct sum of simple algebras. Every finite dimensional nil-semisimple alternative algebra is isomorphic to a direct sum of simple algebras, where every simple algebra is either a matrix algebra over a skew-field or a Cayley–Dickson algebra over its center.

12. Let A be a finite dimensional alternative algebra over a field F. If the quotient algebra $A/\operatorname{Nil} A$ is separable over F, then there exists a subalgebra B of A such that B is isomorphic to $A/\operatorname{Nil} A$ and $A = B \oplus \operatorname{Nil} A$ (vector space direct sum).
13. Every alternative bimodule over a separable alternative algebra is completely reducible (as in the case of associative algebras).
14. Let A be a finite dimensional alternative algebra, let M be a faithful irreducible A-bimodule, and let (λ, ρ) be the associated birepresentation of A. Either M is an associative bimodule over A (which must then be associative), or one of the following holds:
    (a) The algebra A is an algebra of generalized quaternions, λ is a (right) associative irreducible representation of A, and $\rho(x) = \lambda(\overline{x})$ for every $x \in A$.
    (b) The algebra $A = \mathbb{O}$ is a Cayley–Dickson algebra and M is isomorphic to $\operatorname{Reg}(\mathbb{O})$.
15. Every simple alternative algebra (of any dimension) is either associative or is isomorphic to a Cayley–Dickson algebra over its center.

86.5 Jordan Algebras

In this section, we assume that the base field F has characteristic $\neq 2$.

Definitions:

A **Jordan algebra** is a commutative nonassociative algebra satisfying the **Jordan identity**

$$(x^2 y)x = x^2(yx).$$

The **linearization on** x of the Jordan identity is

$$2((xz)y)x + (x^2 y)z = 2(xz)(xy) + x^2(yz).$$

A Jordan algebra J is **special** if it is isomorphic to a subalgebra of the algebra A^+ for some associative algebra A; otherwise, it is **exceptional**.

Facts: [BK66], [Jac68], [ZSS82], [McC04] Additional facts about Jordan algebras are given in Section 86.1, and facts about noncommutative Jordan algebras are given in Section 86.6:

1. (Zelmanov's Simple Theorem) Every simple Jordan algebra (of any dimension) is isomorphic to one of the following: (a) an algebra of a bilinear form, (b) an algebra of Hermitian type, or (c) an Albert algebra. For definitions see Examples 3, 4, and 5.
2. Let J be a Jordan algebra. Consider the regular birepresentation $x \mapsto L_x$, $x \mapsto R_x$ of the algebra J. Commutativity and the Jordan identity imply that for all $x, y \in J$ we have

$$L_x = R_x, \qquad [R_x, R_{x^2}] = 0, \qquad R_{x^2 y} - R_y R_{x^2} + 2R_x R_y R_x - 2R_x R_{yx} = 0.$$

   Linearizing the last equation on x we see that for all $x, y, z \in J$ we have

$$R_{(xz)y} - R_y R_{xz} + R_x R_y R_z + R_z R_y R_x - R_x R_{yz} - R_z R_{yx} = 0.$$

3. For every $k \geq 1$, the operator R_{x^k} belongs to the subalgebra $A \subseteq \operatorname{End} J$ generated by R_x and R_{x^2}. Since A is commutative, we have $[R_{x^k}, R_{x^\ell}] = 0$ for all $k, \ell \geq 1$, which can be written as $(x^k, J, x^\ell) = \{0\}$.

4. It follows from the previous fact that every Jordan algebra is power associative and the radical $\operatorname{Nil} J$ is defined.
5. Let J be a finite dimensional Jordan algebra. As for alternative algebras, we have

$$\operatorname{Nil} J = \operatorname{Solv} J = \operatorname{Nilp} J,$$

that is, the radical $\operatorname{Nil} J$ is nilpotent. The quotient algebra $J/\operatorname{Nil} J$ is semisimple, that is, isomorphic to a direct sum of simple algebras. If the quotient algebra $J/\operatorname{Nil} J$ is separable over F, then there exists a subalgebra B of J such that B is isomorphic to $J/\operatorname{Nil} J$ and $J = B \oplus \operatorname{Nil} J$ (vector space direct sum).
6. If a Jordan algebra J contains an idempotent e, the operator R_e satisfies the equation $R_e(2R_e - 1)\,(R_e - 1) = 0$, and the algebra J has the following analogue of the Pierce decomposition from the theory of associative algebras:

$$J = J_1 \oplus J_{1/2} \oplus J_0, \quad \text{where} \quad J_i = J_i(e) = \{x \in J \mid xe = ix\}.$$

For $i, j = 0, 1$ $(i \neq j)$, we have the inclusions

$$J_i^2 \subseteq J_i, \quad J_i J_{1/2} \subseteq J_{1/2}, \quad J_i J_j = \{0\}, \quad J_{1/2}^2 \subseteq J_1 + J_2.$$

More generally, if J has unit $1 = \sum_{i=1}^n e_i$ where e_i are orthogonal idempotents, then

$$J = \bigoplus_{i \leq j} J_{ij}, \quad \text{where} \quad J_{ii} = J_1(e_i), \qquad J_{ij} = J_{1/2}(e_i) \cap J_{1/2}(e_j) \qquad \text{for } i \neq j,$$

and the components J_{ij} are multiplied according to the rules

$$J_{ii}^2 \subseteq J_{ii}, \quad J_{ij}J_{ii} \subseteq J_{ij}, \quad J_{ij}^2 \subseteq J_{ii} + J_{jj}, \quad J_{ii}J_{jj} = \{0\} \quad \text{for distinct } i, j;$$
$$J_{ij}J_{jk} \subseteq J_{ik}, \quad J_{ij}J_{kk} = \{0\}, \quad J_{ij}J_{k\ell} = \{0\} \quad \text{for distinct } i, j, k, \ell.$$

7. Every Jordan algebra that contains >3 strongly connected orthogonal idempotents is special. (Orthogonal idempotents e_1, e_2 are **strongly connected** if there exists an element $u_{12} \in J_{12}$ for which $u_{12}^2 = e_1 + e_2$.)
8. (Coordinatization Theorem) Let J be a Jordan algebra with unit $1 = \sum_{i=1}^n e_i$ $(n \geq 3)$, where the e_i are mutually strongly connected orthogonal idempotents. Then J is isomorphic to the Jordan algebra $H_n(D)$ of Hermitian $n \times n$ matrices over an alternative algebra D (which is associative for $n > 3$) with involution $*$ such that $H(D, *) \subseteq N(D)$, where $N(D)$ is the associative center of D.
9. Every Jordan bimodule over a separable Jordan algebra is completely reducible, and the structure of irreducible bimodules is known.

Examples:

1. **The algebra A^+.** If A is an associative algebra, then the algebra A^+ is a Jordan algebra. Every subspace J of A closed with respect to the operation $x \cdot y = \frac{1}{2}(xy + yx)$ is a subalgebra of the algebra A^+ and every special Jordan algebra J is (up to isomorphism) of this type. The subalgebra of A generated by J is called the *associative enveloping algebra* of J. Properties of the algebras A and A^+ are closely related: A is simple (respectively, nilpotent) if and only if A^+ is simple (respectively, nilpotent).
2. The algebra A^+ may be a Jordan algebra for nonassociative A; for instance, if A is a right alternative (in particular, alternative) algebra, then A^+ is a special Jordan algebra.

3. *The algebra of a bilinear form.* Let X be a vector space of dimension >1 over F, with a symmetric nondegenerate bilinear form $f(x, y)$. Consider the vector space direct sum $J(X, f) = F \oplus X$, and define on it a multiplication by assuming that the unit element $1 \in F$ is the unit element of $J(X, f)$ and by setting $xy = f(x, y)1$ for any $x, y \in X$. Then $J(X, f)$ is a simple special Jordan algebra; its associative enveloping algebra is the Clifford algebra $C(X, f)$ of the bilinear form f. When $F = \mathbb{R}$ and $f(x, y)$ is the ordinary dot product on X, the algebra $J(X, f)$ is called a *spin-factor*.
4. *Algebras of Hermitian type.* Let A be an associative algebra with involution $*$. The subspace $H(A, *) = \{x \in A \,|\, x^* = x\}$ of $*$-symmetric elements is closed with respect to the Jordan multiplication $x \cdot y$ and, therefore, is a special Jordan algebra. For example, let D be an associative composition algebra with involution $x \mapsto \overline{x}$ and let $D^{n\times n}$ be the algebra of $n \times n$ matrices over D. Then the mapping $S\colon (x_{ij}) \mapsto (\overline{x_{ji}})$ is an involution of $D^{n\times n}$ and the set of D-Hermitian matrices $H_n(D) = H(D^{n\times n}, S)$ is a special Jordan algebra. If A is $*$-simple (if it contains no proper ideal I with $I^* \subseteq I$), then $H(A, *)$ is simple. In particular, all the algebras $H_n(D)$ are simple. Every algebra A^+ is isomorphic to the algebra $H(B, *)$ where $B = A \oplus A^{\mathrm{opp}}$ (algebra direct sum) and $(x_1, x_2)^* = (x_2, x_1)$.
5. *Albert algebras.* If $D = \mathbb{O}$ is a Cayley–Dickson algebra, then the algebra $H_n(\mathbb{O})$ of Hermitian matrices over D is a Jordan algebra only for $n \leq 3$. For $n = 1, 2$ the algebras are isomorphic to algebras of bilinear forms and are, therefore, special. The algebra $H_3(\mathbb{O})$ is exceptional (not special). An algebra J is called an Albert algebra if $K \otimes_F J \cong H_3(\mathbb{O})$ for some extension K of the field F. Every Albert algebra is simple, exceptional, and has dimension 27 over its center.

86.6 Power Associative Algebras, Noncommutative Jordan Algebras, and Right Alternative Algebras

A natural generalization of Jordan algebras is the class of algebras that satisfy the Jordan identity but which are not necessarily commutative. If the algebra has a unit element, then the Jordan identity easily implies the flexible identity. The right alternative algebras have been the most studied among the power associative algebras that do not satisfy the flexible identity.

As in the previous section, we assume that F is a field of characteristic $\neq 2$.

Definitions:

A **noncommutative Jordan algebra** is an algebra satisfying the flexible and Jordan identities. In this definition the Jordan identity may be replaced by any of the identities

$$x^2(xy) = x(x^2y), \qquad (yx)x^2 = (yx^2)x, \qquad (xy)x^2 = (x^2y)x.$$

A subspace V of an algebra A is **right nilpotent** if $V^{\langle n\rangle} = \{0\}$ for some $n \geq 1$, where $V^{\langle 1\rangle} = V$ and $V^{\langle n+1\rangle} = V^{\langle n\rangle}V$.

Facts: [Sch66], [ZSS82], [KS95]

1. Let A be a finite dimensional power associative algebra with a bilinear symmetric form (x, y) satisfying the following conditions:
   (a) $(xy, z) = (x, yz)$ for all $x, y, z \in A$.
   (b) $(e, e) \neq 0$ for every idempotent $e \in A$.

(c) $(x, y) = 0$ if the product xy is nilpotent.

Then $\mathrm{Nil}\, A = \mathrm{Nil}\, A^+ = \{x \in A \mid (x, A) = \{0\}\}$, and if F has characteristic $\neq 2, 3, 5$, then the quotient algebra $A/\mathrm{Nil}\, A$ is a noncommutative Jordan algebra.

2. Let A be a finite dimensional nil-semisimple flexible power associative algebra over an infinite field of characteristic $\neq 2, 3$. Then A has a unit element and is a direct sum of simple algebras, each of which is either a noncommutative Jordan algebra or (in the case of positive characteristic) an algebra of degree 2.
3. The structure of arbitrary finite dimensional nil-semisimple power associative algebras is still unclear. In particular, it is not known whether they are semisimple. It is known that in this case new simple algebras arise even in characteristic zero.
4. An algebra A is a noncommutative Jordan algebra if and only if it is flexible and the corresponding plus-algebra A^+ is a Jordan algebra.
5. Let A be a noncommutative Jordan algebra. For $x \in A$, the operators R_x, L_x, L_{x^2} generate a commutative subalgebra in the multiplication algebra $M(A)$, containing all the operators R_{x^k} and L_{x^k} for $k \geq 1$.
6. Every noncommutative Jordan algebra is power associative.
7. Let A be a finite dimensional nil-semisimple noncommutative Jordan algebra over F. Then A has a unit element and is a direct sum of simple algebras. If F has characteristic 0, then every simple summand is either a (commutative) Jordan algebra, a quasi-associative algebra (see Example 3), or a quadratic flexible algebra. In the case of positive characteristic, there are more examples of simple noncommutative Jordan algebras.
8. Unlike alternative and Jordan algebras, an analogue of the Wedderburn Principal Theorem on splitting of the nil radical does not hold in general for noncommutative Jordan algebras.
9. Every quasi-associative algebra (see Example 3) is a noncommutative Jordan algebra.
10. Every flexible quadratic algebra is a noncommutative Jordan algebra.
11. The right multiplication operators in every right alternative algebra A satisfy

$$R_{x^2} = R_x^2, \qquad R_{x \cdot y} = R_x \cdot R_y,$$

where $x \cdot y = \frac{1}{2}(xy + yx)$ is the multiplication in the algebra A^+. (Recall that, in this section, we assume that the characteristic of the base field is $\neq 2$.)

12. If A is a right alternative algebra (respectively, noncommutative Jordan algebra), then its unital hull $A^\sharp$ is also right alternative (respectively, noncommutative Jordan).
13. If A is a right alternative algebra, then the mapping $x \mapsto R_x$ is a homomorphism of the algebra A^+ into the special Jordan algebra $R(A)^+$. If A has a unit element, then this mapping is injective. For every right alternative algebra A, the algebra A^+ is embedded into the algebra $R(A^\sharp)^+$ and, hence, is a special Jordan algebra.
14. Every right alternative algebra A satisfies the identity

$$R_{x^k} R_{x^\ell} = R_{x^{k+\ell}} \quad \text{for any } x \in A \quad \text{and} \quad k, \ell \geq 1.$$

Therefore, A is power associative and the nil radical $\mathrm{Nil}\, A$ is defined.

15. Let A be an arbitrary right alternative algebra. Then the quotient algebra $A/\mathrm{Nil}\, A$ is alternative. In particular, every right alternative algebra without nilpotent elements is alternative.
16. Every simple right alternative algebra that is not a nil algebra is alternative (and, hence, either associative or a Cayley–Dickson algebra). The nonnil restriction is essential: There exists a nonalternative simple right alternative nil algebra.
17. A finite dimensional right alternative nil algebra is right nilpotent and, therefore, solvable, but such an algebra can be nonnilpotent. In particular, the subclass *Nilp* is not radical in the class of finite dimensional right alternative algebras.

Examples:

1. The Suttles algebra (Example 86.2.5) is a power associative algebra that is not a noncommutative Jordan algebra. For another example, see Example 5 below.
2. The class of noncommutative Jordan algebras contains, apart from Jordan algebras, all alternative algebras (and, thus, all associative algebras) and all anticommutative algebras.
3. *Quasi-associative algebras.* Let A be an algebra over a field F and let $a \in F$, $a \neq \frac{1}{2}$. Define a new multiplication on A as follows:

   $$x \cdot_a y = axy + (1-a)yx,$$

   and denote the resulting algebra by A^a. The passage from A to A^a is reversible: $A = (A^a)^b$ for $b = a/(2a-1)$. Properties of A and A^a are closely related: The ideals (respectively, subalgebras) of A are those of A^a; the algebra A^a is nilpotent (respectively, solvable, simple) if and only if the same holds for A. If A is associative, then A^a is a noncommutative Jordan algebra; furthermore, if the identity $[[x,y],z] = 0$ does not hold in A, then A^a is not associative. In particular, if A is a simple noncommutative associative algebra, then A^a is an example of a simple nonassociative noncommutative Jordan algebra. The algebras of the form A^a for an associative algebra A are **split** quasi-associative algebras. More generally, an algebra A is quasi-associative if it has a scalar extension, which is a split quasi-associative algebra.
4. *Generalized Cayley–Dickson algebras.* For $a_1, \ldots, a_n \in F - \{0\}$ let

   $$A(a_1) = (F, a_1), \quad \ldots, \quad A(a_1, \ldots, a_n) = (A(a_1, \ldots, a_{n-1}), a_n),$$

   be the algebras obtained from F by successive application of the Cayley–Dickson process (Example 86.1.2). Then $A(a_1, \ldots, a_n)$ is a central simple quadratic noncommutative Jordan algebra of dimension 2^n.
5. Let V be a vector space of dimension $2n$ over a field F with a nondegenerate skew-symmetric bilinear form (x,y). On the vector space direct sum $A = F \oplus V$ define a multiplication (as for the Jordan algebra of bilinear form) by letting the unit element 1 of F be the unit of A and by setting $xy = (x,y)1$ for any $x, y \in V$. Then A is a simple quadratic algebra (and, hence, it is power associative), but A is not flexible and, thus, is not a noncommutative Jordan algebra.

86.7 Malcev Algebras

Some of the theory of Malcev algebras generalizes the theory of Lie algebras. For information about Lie algebras, the reader is advised to consult Chapter 87.

Definitions:

A **Malcev algebra** is an anticommutative algebra satisfying the identity

$$J(x,y,xz) = J(x,y,z)x, \quad \text{where} \quad J(x,y,z) = (xy)z + (yz)x + (zx)y.$$

In a **left-normalized product** we omit the parenthesis, for example,

$$xyzx = ((xy)z)x, \qquad yzxx = ((yz)x)x.$$

A **representation** of a Malcev algebra A is a linear mapping $\rho\colon A \to \operatorname{End} V$ satisfying the following identity for all $x, y, z \in A$:

$$\rho(xy \cdot z) = \rho(x)\rho(y)\rho(z) - \rho(z)\rho(x)\rho(y) + \rho(y)\rho(zx) - \rho(yz)\rho(x).$$

We call V a **Malcev module** for A. The anticommutativity of A implies that the notion of a Malcev module is equivalent to that of Malcev bimodule; we set $xv = -vx$ for all $x \in A$, $v \in V$.

The **Killing form** $K(x, y)$ on a Malcev algebra A is defined (as for a Lie algebra) by

$$K(x, y) = \operatorname{trace}(R_x R_y).$$

Facts: [KS95], [She00], [PS04], [SZ06]

1. After expanding the Jacobians, the Malcev identity takes the form

   $$xyzx + yzxx + zxxy = xy \cdot xz,$$

   (using our convention on left-normalized products). If F has characteristic $\neq 2$, the Malcev identity is equivalent to the more symmetric identity

   $$xyzt + yztx + ztxy + txyz = xz \cdot yt.$$

2. Any two elements in a Malcev algebra generate a Lie subalgebra.
3. The structure theory of finite dimensional Malcev algebras repeats the main features of the corresponding theory for Lie algebras. For any alternative algebra A, the minus algebra A^- is a Malcev algebra. Let $\mathbb{O} = \mathbb{O}(a, b, c)$ be a Cayley–Dickson algebra over a field F of characteristic $\neq 2$. Then $\mathbb{O} = F \oplus M$ (vector space direct sum), where $M = \{x \in \mathbb{O} \,|\, t(x) = 0\}$. The subspace M is a subalgebra (in fact, an ideal) of the Malcev algebra $\mathbb{O}^-$, and $M \cong \mathbb{O}^-/F$ (in fact, $\mathbb{O}^-$ is the Malcev algebra direct sum of the ideals F and M). The Malcev algebra $M = M(a, b, c)$ is central simple and has dimension 7 over F; if F has characteristic $\neq 3$, then M is not a Lie algebra.
4. Every central simple Malcev algebra of characteristic $\neq 2$ is either a Lie algebra or an algebra $M(a, b, c)$. There are no non-Lie simple Malcev algebras in characteristic 3.
5. Two Malcev algebras $M(a, b, c)$, $M(a', b', c')$ are isomorphic if and only if the corresponding Cayley–Dickson algebras $\mathbb{O}(a, b, c)$, $\mathbb{O}(a', b', c')$ are isomorphic.
6. Let A be a finite dimensional Malcev algebra over a field F of characteristic 0 and let $\operatorname{Solv} A$ be the solvable radical of A. The algebra A is semisimple (it decomposes into a direct sum of simple algebras) if and only if $\operatorname{Solv} A = \{0\}$ (in fact, this is often used as the definition of "semisimple" for Malcev algebras, following the terminology for Lie algebras). If the quotient algebra $A/\operatorname{Solv} A$ is separable, then A contains a subalgebra $B \cong A/\operatorname{Solv} A$ and $A = B \oplus \operatorname{Solv} A$ (vector space direct sum).
7. The Killing form $K(x, y)$ is symmetric and associative:

   $$K(x, y) = K(y, x), \qquad K(xy, z) = K(x, yz).$$

   The algebra A is semisimple if and only if the form $K(x, y)$ is nondegenerate. For the solvable radical we have $\operatorname{Solv} A = \{\, x \in A \,|\, K(x, A^2) = \{0\} \,\}$. In particular, A is solvable if and only if $K(A, A^2) = \{0\}$.
8. If all the operators $\rho(x)$ for $x \in A$ are nilpotent, then they generate a nilpotent subalgebra in $\operatorname{End} V$ (A acts nilpotently on V). If the representation ρ is almost faithful (that is, $\ker \rho$ does not contain nonzero ideals of A), then A is nilpotent.
9. Every representation of a semisimple Malcev algebra A is completely reducible.
10. If A is a Malcev algebra and V is an A-bimodule, then V is a Malcev module for A if and only if the split null extension $E(A, V)$ is a Malcev algebra.
11. Let A be a Malcev algebra, and let V be a faithful irreducible A-module. Then the algebra A is simple, and either V is a Lie module over A (which must then be a Lie algebra) or one of the following holds:
    (a) $A \cong M(a, b, c)$ and V is a regular A-module.

(b) A is isomorphic to the Lie algebra $sl(2, F)$ with $\dim V = 2$ and $\rho(x) = x^*$, where x^* is the matrix adjoint to $x \in A \subseteq M_2(F)$. (Here the matrix adjoint is defined by the equation $x\,x^* = x^*x = \det(x)I$, where I is the identity matrix.)

12. The *speciality problem* for Malcev algebras is still open: Is every Malcev algebra embeddable into the algebra A^- for some alternative algebra A? This is the generalization of the Poincaré–Birkhoff–Witt theorem for Malcev algebras.

86.8 Akivis and Sabinin Algebras

The theory of Akivis and Sabinin algebras generalizes the theory of Lie algebras and their universal enveloping algebras. For information about Lie algebras, the reader is advised to consult Chapter 87.

Definitions:

An **Akivis algebra** is a vector space A over a field F, together with an anticommutative bilinear operation $A \times A \to A$ denoted $[x, y]$, and a trilinear operation $A \times A \times A \to A$ denoted (x, y, z), satisfying the **Akivis identity** for all $x, y, z \in A$:

$$[[x, y], z] + [[y, z], x] + [[z, x], y] = (x, y, z) + (y, z, x) + (z, x, y) - (x, z, y) - (y, x, z) - (z, y, x).$$

A **Sabinin algebra** is a vector space A over a field F, together with multilinear operations

$$\langle x_1, \ldots, x_m; y, z\rangle \qquad (m \geq 0),$$

satisfying these identities:

$$\langle x_1, \ldots, x_m; y, y\rangle = 0, \tag{86.5}$$

$$\langle x_1, \ldots, x_r, u, v, x_{r+1}, \ldots, x_m; y, z\rangle - \langle x_1, \ldots, x_r, v, u, x_{r+1}, \ldots, x_m; y, z\rangle + \sum_{k=0}^{r} \sum_{s} \langle x_{s(1)}, \ldots, x_{s(k)}, \langle x_{s(k+1)}, \ldots, x_{s(r)}; u, v\rangle, x_{r+1}, \ldots, x_m; y, z\rangle = 0, \tag{86.6}$$

$$K_{u,v,w}\Big[\langle x_1, \ldots, x_r, u; v, w\rangle + \sum_{k=0}^{r} \sum_{s} \langle x_{s(1)}, \ldots, x_{s(k)}; \langle x_{s(k+1)}, \ldots, x_{s(r)}; v, w\rangle, u\rangle\Big] = 0, \tag{86.7}$$

where s is a $(k, r-k)$-shuffle (a permutation of $1, \ldots, r$ satisfying $s(1) < \cdots < s(k)$ and $s(k+1) < \cdots < s(r)$) and the operator $K_{u,v,w}$ denotes the sum over all cyclic permutations. (See Fact 9 below for an alternative formulation of this definition.)

An algebra $\mathcal{F}_{\mathcal{M}}[X]$ from a class $\mathcal{M}$, with a set of generators X, is called the **free algebra** in $\mathcal{M}$ with the set X of free generators, if any mapping of X into an arbitrary algebra $A \in \mathcal{M}$ extends uniquely to a homomorphism of $\mathcal{F}_{\mathcal{M}}[X]$ to A.

Let I be any subset of $\mathcal{F}_{\mathcal{M}}[X]$. The T-**ideal** in $\mathcal{F}_{\mathcal{M}}[X]$ determined by I, denoted by $T = T(I, X)$, is the smallest ideal of $\mathcal{F}_{\mathcal{M}}[X]$ containing all elements of the form $f(x_1, \ldots, x_n)$ for all $f \in I$ and all $x_1, \ldots, x_n \in \mathcal{F}_{\mathcal{M}}[X]$.

Facts: [HS90], [She99], [SU02], [GH03], [Per07], [BHP05], [BDE05]

1. Free algebras may be constructed as follows. Let S be a set of generating elements and let Ω be a set of operation symbols. Let $r\colon \Omega \to \mathbb{N}$ (the nonnegative integers) be the arity function; that is, $\omega \in \Omega$ will represent an n-ary operation for $n = r(\omega)$. The set $W(S, \Omega)$ of nonassociative Ω-words on the set S is defined inductively as follows:

(a) $S \subseteq W(S, \Omega)$.

(b) If $\omega \in \Omega$ and $x_1, \ldots, x_n \in W(S, \Omega)$ where $n = r(\omega)$, then $\omega(x_1, \ldots, x_n) \in W(S, \Omega)$.

Let F be a field and let $F(S, \Omega)$ be the vector space over F with basis $W(S, \Omega)$. For each $\omega \in \Omega$ we define an n-ary operation with $n = r(\omega)$ on $F(S, \Omega)$, denoted by the same symbol ω, as follows: Given any basis elements $x_1, \ldots, x_n \in W(S, \Omega)$, we set the value of ω on the arguments $x_1, \ldots, x_n$ equal to the nonassociative word $\omega(x_1, \ldots, x_n)$, and extend linearly to all of $F(S, \Omega)$. The algebra $F(S, \Omega)$ is the free Ω-algebra on the generating set S over the field F with the operations $\omega \in \Omega$.

2. The quotient algebra $F(S, \Omega)/T(I, S, \Omega)$ is the free $\mathcal{M}$-algebra for the class $\mathcal{M} = \mathcal{M}(I)$ of Ω-algebras defined by the set of identities I.
3. Every subalgebra of a free Akivis algebra is again free.
4. Every Akivis algebra is isomorphic to a subalgebra of *Akivis*(A) for some nonassociative algebra A. This generalizes the Poincaré–Birkhoff–Witt theorem for Lie algebras. The free nonassociative algebra is the universal enveloping algebra of the free Akivis algebra. (See Example 1.)
5. The free nonassociative algebra with generating set X has a natural structure of a (nonassociative) Hopf algebra, generalizing the Hopf algebra structure on the free associative algebra. The *Akivis elements* (the elements of the subalgebra generated by X using the commutator and associator) are properly contained in the *primitive elements* (the elements satisfying $\Delta(x) = x \otimes 1 + 1 \otimes x$ where Δ is the co-multiplication). The Akivis elements and the primitive elements have a natural structure of an Akivis algebra. The primitive elements have the additional structure of a Sabinin algebra.
6. The Witt dimension formula for free Lie algebras (the primitive elements in the free associative algebra) has a generalization to the primitive elements in the free nonassociative algebra.
7. Sabinin algebras are a nonassociative generalization of Lie algebras in the following sense: The tangent space at the identity of any local analytic loop (without associativity assumptions) has a natural structure of a Sabinin algebra, and the classical correspondence between Lie groups and Lie algebras generalizes to this case.
8. Every Sabinin algebra arises as the subalgebra of primitive elements in some nonassociative Hopf algebra.
9. Another (equivalent) way to define Sabinin algebras, which exploits the Hopf algebra structure, is as follows. Let A be a vector space and let $T(A)$ be the tensor algebra of A. We write $\Delta\colon T(A) \to T(A) \otimes T(A)$ for the co-multiplication on $T(A)$: the algebra homomorphism that extends the diagonal mapping $\Delta\colon u \mapsto 1 \otimes u + u \otimes 1$ for $u \in A$. We will use the Sweedler notation and write $\Delta(x) = \sum x_{(1)} \otimes x_{(2)}$ for any $x \in T(A)$. Then A is a Sabinin algebra if it is equipped with a trilinear mapping

$$T(A) \otimes A \otimes A \to A, \qquad x \otimes y \otimes z \mapsto \langle x; y, z \rangle, \qquad \text{for } x \in T(A) \text{ and } y, z \in A,$$

satisfying the identities

$$\langle x; y, y \rangle = 0, \tag{86.8}$$

$$\langle x \otimes u \otimes v \otimes x'; y, z \rangle - \langle x \otimes v \otimes u \otimes x'; y, z \rangle + \sum \langle x_{(1)} \otimes \langle x_{(2)}; u, v \rangle \otimes x'; y, z \rangle \\ = 0, \tag{86.9}$$

$$K_{u,v,w} \left[\langle x \otimes u; v, w \rangle + \sum \langle x_{(1)}; \langle x_{(2)}; v, w \rangle, u \rangle \right] = 0, \tag{86.10}$$

where $x, x' \in T(A)$ and $u, v, w, y, z \in A$. Identities (8 to 10) exploit the Sweedler notation to express identities (5 to 7) in a more compact form.

Examples:

1. Any nonassociative algebra A becomes an Akivis algebra $\mathit{Akivis}(A)$ if we define $[x, y]$ and (x, y, z) to be the commutator $xy - yx$ and the associator $(xy)z - x(yz)$. If A is an associative algebra, then the trilinear operation of $\mathit{Akivis}(A)$ is identically zero; in this case, the Akivis identity reduces to the Jacobi identity, and so $\mathit{Akivis}(A)$ is a Lie algebra. If A is an alternative algebra, then the alternating property of the associator shows that the right side of the Akivis identity reduces to $6(x, y, z)$.
2. Every Lie algebra is an Akivis algebra with the identically zero trilinear operation. Every Malcev algebra (over a field of characteristic $\neq 2, 3$) is an Akivis algebra with the trilinear operation equal to $\frac{1}{6}J(x, y, z)$.
3. Every Akivis algebra A is a Sabinin algebra if we define

$$\langle a, b\rangle = -[a, b], \qquad \langle x; a, b\rangle = (x, b, a) - (x, a, b), \qquad \langle x_1, \dots, x_m; a, b\rangle = 0 \ (m > 1),$$

   for all $a, b, x, x_i \in A$.
4. Let L be a Lie algebra with a subalgebra $H \subseteq L$ and a subspace $V \subseteq L$ for which $L = H \oplus V$. We write $P_V : L \to V$ for the projection onto V with respect to this decomposition of L. We define an operation

$$\langle -, -; -\rangle : T(V) \otimes V \otimes V \to V$$

   by (using the Sweedler notation again)

$$\{x \otimes a \otimes b\} + \sum \left\{x_{(1)} \otimes \langle x_{(2)}; a, b\rangle\right\} = 0,$$

   where for $x = x_1 \otimes \cdots \otimes x_n \in T(V)$ we write

$$\{x\} = P_V([x_1, [\dots, [x_{n-1}, x_n]] \cdots]).$$

   Then the vector space V together with the operation $\langle -, -; -\rangle$ is a Sabinin algebra, and every Sabinin algebra can be obtained in this way.

86.9 Computational Methods

For homogeneous multilinear polynomial identities of degree n, the number of associative monomials is $n!$ and the number of association types is C_n (the Catalan number); hence, the number of nonassociative monomials grows superexponentially:

$$n! \cdot \frac{1}{n}\binom{2n-2}{n-1} = \frac{(2n-2)!}{(n-1)!} > n^{n-1}.$$

One way to reduce the size of the computations is to apply the theory of superalgebras [Vau98]. Another technique is to decompose the space of multilinear identities into irreducible representations of the symmetric group S_n. The application of the representation theory of the symmetric group to the theory of polynomial identities for algebras was initiated in 1950 by Malcev and Specht. The computational implementation of these techniques was pioneered by Hentzel in the 1970s [Hen77]; for detailed discussions of recent applications, see [HP97] and [BH04]. Another approach has been implemented in the Albert system [Jac03]. In this section, we present three small examples ($n \leq 4$) of computational techniques in nonassociative algebra.

Examples:

1. *The identities of degree 3 satisfied by the division algebra of real octonions.*
   There are 12 distinct multilinear monomials of degree 3 for a nonassociative algebra:

   $$(xy)z,\ (xz)y,\ (yx)z,\ (yz)x,\ (zx)y,\ (zy)x,\ x(yz),\ x(zy),\ y(xz),\ y(zx),\ z(xy),\ z(yx).$$

   We create a matrix of size 8×12 and initialize it to zero; the columns correspond to the nonassociative monomials. We use a pseudorandom number generator to produce three octonions x, y, z represented as vectors with respect to the standard basis 1, i, j, k, ℓ, m, n, p. We store the evaluation of monomial j in column j of the matrix. For example, generating random integers from the set $\{-1, 0, 1\}$ using the base 3 expansion of $1/\sqrt{2}$ gives

   $$x = [1, -1, 0, -1, -1, 1, 0, 0], \quad y = [-1, 1, 1, 1, 0, 0, 1, 0], \quad z = [-1, 1, 1, 1, 0, 0, 0, -1].$$

   Evaluation of the monomials gives the matrix in Table 86.1; its reduced row echelon form appears in Table 86.2. The nullspace contains the identities satisfied by the octonion algebra: the span of the rows of the matrix in Table 86.3. These rows represent the linearizations of the right alternative identity (row 1), the left alternative identity (row 2), and the flexible identity (row 5), together with the assocyclic identities $(x, y, z) = (y, z, x)$ and $(x, y, z) = (z, x, y)$ (rows 3 and 4).

TABLE 86.1 The octonion evaluation matrix.

$$\begin{bmatrix}

2. *The identities of degree 4 satisfied by the Jordan product $x * y = xy + yx$ in every associative algebra over a field of characteristic 0.*
   The operation $x * y$ satisfies commutativity in degree 2, and there are no new identities of degree 3, so we consider degree 4. There are 15 distinct multilinear monomials for a com-

TABLE 86.3 A basis for the nullspace of the octonion evaluation matrix.

$$\begin{bmatrix} -1 & -1 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ -1 & 0 & -1 & 0 & 0 & 0 & 1 & 0 & 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & -1 & 0 & 0 & -1 & 0 & 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 0 & -1 & 0 & -1 & 0 & 0 & 0 & 1 & 0 \\ -1 & 0 & 0 & 0 & 0 & -1 & 1 & 0 & 0 & 0 & 0 & 1 \end{bmatrix}$$

mutative nonassociative operation, 12 for association type $((--)-)-$ and 3 for association type $(--)(--)$:

$$((w{*}x){*}y){*}z,\ ((w{*}x){*}z){*}y,\ ((w{*}y){*}x){*}z,\ ((w{*}y){*}z){*}x,\ ((w{*}z){*}x){*}y,$$
$$((w{*}z){*}y){*}x,\ ((x{*}y){*}w){*}z,\ ((x{*}y){*}z){*}w,\ ((x{*}z){*}w){*}y,\ ((x{*}z){*}y){*}w,$$
$$((y{*}z){*}x){*}w,\ ((y{*}z){*}w){*}x,\ (w{*}x){*}(y{*}z),\ (w{*}y){*}(x{*}z),\ (w{*}z){*}(x{*}y).$$

When each of these monomials is expanded in terms of the associative product, there are 24 possible terms, namely the permutations of w, x, y, z in lexicographical order: $wxyz$, $\ldots$, $zyxw$. We construct a 24×15 matrix in which the i, j entry is the coefficient of the ith associative monomial in the expansion of the jth commutative monomial (see Table 86.4). The nontrivial identities of degree 4 satisfied by $x * y$ correspond to the nonzero vectors in the nullspace. The reduced row echelon form appears in Table 86.5. The rank is 11 and, so, the nullspace has dimension 4. A basis for the nullspace consists of the rows of Table 86.6. The first row represents the linearization of the Jordan identity; this is the only identity that involves monomials of both association types. (This proves that the plus algebra A^+ of any associative algebra A is a Jordan algebra.) The Jordan identity implies the identities in the other three rows, which are permuted forms of the identity

$$w{*}(x{*}(yz)) - x{*}(w{*}(yz)) = (w{*}(x{*}y)){*}z - (x{*}(w{*}y)){*}z + y{*}(w{*}(x{*}z)) - y{*}(x{*}(w{*}z));$$

that is, the commutator of multiplication operators is a derivation.

3. *The identities of degree 4 satisfied by the commutator* $[x, y] = xy - yx$ *in every alternative algebra over a field of characteristic zero.*

The group algebra $\mathbb{Q}S_n$ decomposes as a direct sum of full matrix algebras of size $d_\lambda \times d_\lambda$ where the index λ runs over all partitions λ of the integer n; here d_λ is the dimension of the irreducible representation of S_n corresponding to the partition λ. We choose the "natural representation" to fix a particular decomposition. For each λ there is a projection p_λ from $\mathbb{Q}S_n$ onto the matrix algebra of size $d_\lambda \times d_\lambda$. In the case $n = 4$ the partitions and the dimensions of the corresponding irreducible representation S_4 are given in Table 86.7. For a nonassociative operation in degree 4 there are 5 association types:

$$((--)-)-, \quad (-(--))-, \quad (--)(--), \quad -((--)-), \quad -(-(--)),$$

and so any nonassociative identity can be represented as an element of the direct sum of 5 copies of $\mathbb{Q}S_n$: Given a partition λ, the nonassociative identity projects via p_λ to a matrix of size $d_\lambda \times 5d_\lambda$. For an anticommutative operation in degree 4 there are 2 association types:

$$[[[-,-],-],-], \quad [[-,-],[-,-]],$$

TABLE 86.7 Partitions of 4 and irreducible representations of S_4.

λ	4	31	22	211	1111
d_λ	1	3	2	3	1

and so any anticommutative identity projects via p_λ to a matrix of size $d_\lambda \times 2d_\lambda$. The linearizations of the left and right alternative identities are

$$L(x,y,z) = (xy)z - x(yz) + (yx)z - y(xz), \qquad R(x,y,z) = (xy)z - x(yz) + (xz)y - x(zy).$$

Each of these can be "lifted" to degree 4 in five ways; for $L(a,b,c)$ we have

$$wL(x,y,z), \quad L(xw,y,z), \quad L(x,yw,z), \quad L(x,y,zw), \quad L(x,y,z)w;$$

and similarly for $R(x,y,z)$. Altogether we have 10 lifted alternative identities that project via p_λ to a matrix of size $10d_\lambda \times 5d_\lambda$. Using the commutator to expand the two anticommutative association types gives

$$\begin{aligned}
[[[x,y],z],w] &= ((xy)z)w - ((yx)z)w - (z(xy))w + (z(yx))w \\
&\quad - w((xy)z) + w((yx)z) + w(z(xy)) - w(z(yx)), \\
[[x,y],[z,w]] &= (xy)(zw) - (yx)(zw) - (xy)(wz) + (yx)(wz) \\
&\quad - (zw)(xy) + (zw)(yx) + (wz)(xy) - (wz)(yx).
\end{aligned}$$

Given a partition λ we can store these two relations in a matrix of size $2d_\lambda \times 7d_\lambda$: We use all 7 association types, store the right sides of the relations in the first 5 types, and $-I$ (I is the identity matrix) in type 6 (respectively, 7) for the first (respectively, second) expansion. For each partition λ, all of this data can be stored in a matrix A_λ of size $12d_\lambda \times 7d_\lambda$, which is schematically displayed in Table 86.8. We compute the reduced row echelon form of A_λ: Let i be the largest number for which rows $1-i$ of RREF(A_λ) have a nonzero entry in the first 5 association types. Then the remaining rows of RREF(A_λ) have only zero entries in the first 5 types; if one of these rows contains nonzero entries in the last 2 types, this row represents an identity that is satisfied by the commutator in every alternative algebra. However, such an identity may be a consequence of the obvious anticommutative identities:

$$[[[x,y],z],w] + [[[y,x],z],w] = 0,$$
$$[[x,y],[z,w]] + [[y,x],[z,w]] = 0, \qquad [[x,y],[z,w]] + [[z,w],[x,y]] = 0.$$

TABLE 86.8 The matrix of Malcev identities for partition λ.

$$A_\lambda = \left[\begin{array}{c|cc}
 & 0 & 0 \\
\text{Lifted alternative identities} & \vdots & \vdots \\
 & 0 & 0 \\
\hline
\text{Expansion of } [[[x,y],z],w] & -I & 0 \\
\text{Expansion of } [[x,y],[z,w]] & 0 & -I
\end{array}\right]$$

These identities are represented by a matrix of size $3d_\lambda \times 7d_\lambda$ in which the first $5d_\lambda$ columns are zero. We need to determine if any of the rows $i+1$ to $12d_\lambda$ of $\mathrm{RREF}(A_\lambda)$ do not lie in the row space of the matrix of anticommutative identities. If such a row exists, it represents a nontrivial identity satisfied by the commutator in every alternative algebra. For example, consider the partition $\lambda = 22$ ($d_\lambda = 2$). The 24×14 matrix A_λ for this partition appears in Table 86.9, and its reduced row echelon form appears in Table 86.10.

TABLE 86.9 The lifted and expansion identities for partition $\lambda = 22$.

0 & 0 & -1 & -1 & 1 & 0 & 1 & 1 & -1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & -1 & -1 & 1 & 0 & 1 & 1 & -1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 1 & -1 & 0 & 0 & -1 & 0 & 0 & 0 & 0 \\
1 & 1 & -1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & -1 & -1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\hline
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\
1 & 2 & -1 & 1 & 0 & 0 & 1 & -1 & -1 & -2 & 0 & -1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -1
\end{array}\right]$$

The 6×14 matrix representing the anticommutative identities for this partition appears in Table 86.11, and its reduced row echelon form appears in Table 86.12. Comparing the last four rows of Table 86.10 with Table 86.12, we see that there is one new identity for $\lambda = 22$ represented by the third-last row of Table 86.10. Similar computations for the other partitions show that there is one nontrivial identity for partition $\lambda = 211$ and no nontrivial identities for the other partitions. The two identities from partitions 22 and 211 are the irreducible components of the Malcev identity: The submodule generated by the linearization of the Malcev identity (in the S_4-module of all multilinear anticommutative polynomials of degree 4) is the direct sum of two irreducible submodules corresponding to these two partitions.

A Lie algebra is a (nonassociative) algebra satisfying $x^2 = 0$ for all elements x of the algebra (which implies anticommutativity) and the Jacobi identity. Lie algebras arise naturally as (vector) subspaces of associative algebras closed under the commutator operation $[a, b] = ab - ba$. The finite-dimensional simple Lie algebras over algebraically closed fields of characteristic zero occur in many applications. This chapter outlines the structure, classification, and representation theory of these algebras. We also give examples of other types of algebras, e.g., one class of infinite-dimensional simple algebras and one class of finite-dimensional simple Lie algebras over fields of prime characteristic. Section 87.1 is devoted to general definitions about Lie algebras. Section 87.2 discusses semisimple and simple algebras. This section includes the classification of finite-dimensional simple Lie algebras over algebraically closed fields of characteristic zero. Section 87.3 discusses module theory and includes the classification of finite-dimensional irreducible modules for the aforementioned algebras as well as the explicit construction of some of these modules. Section 87.4 discusses graded algebras and modules and uses this formalism to present results on dimensions of irreducible modules.

87.1 Basic Concepts

Unless specified otherwise, F denotes an arbitrary field. All vector spaces and algebras are over F. The reader is referred to Chapter 86 for definitions of many basic algebra terms.

Definitions:

Let A be an algebra over a field F. An **automorphism** is an algebra isomorphism of A to itself. The set of all automorphisms of A is denoted $Aut(A)$.

A linear transformation $D : A \to A$ is a **derivation** of A if $D(ab) = D(a)b + aD(b)$ for all $a, b \in A$. The set of all derivations of A is denoted $Der(A)$.

Let A be an associative algebra and X be a subset of A. Then the smallest ideal of A containing X is denoted by $< X >$ and called the **ideal generated by** X.

Let V be a vector space over a field F. Let $V^{\otimes n}$ denote the tensor product of n copies of V and set $T(V) = F1 + \sum_{n=1}^{\infty} V^{\otimes n}$. Define a linear map $T(V) \otimes T(V) \to T(V), u \otimes v \mapsto uv$, by $1u = u1 = u$ for all $u \in T(V)$ and

$$(v_1 \otimes \ldots \otimes v_m)(u_1 \otimes \ldots \otimes u_n) = v_1 \otimes \ldots \otimes v_m \otimes u_1 \otimes \ldots \otimes u_n$$

whenever $m, n \geq 1, v_1, \ldots, v_m, u_1, \ldots, u_n \in V$. $T(V)$ is the **tensor algebra** on the vector space V. This algebra is defined, and denoted $\bigotimes V$, in Section 14.9.

An algebra L over a field F with product $[\ ,\ ] : L \times L \to L$, $(a, b) \mapsto [a, b]$ is a **Lie algebra** if it satisfies both

$$[a, a] = 0$$

and

$$[a, [b, c]] + [b, [c, a]] + [c, [a, b]] = 0 \qquad (\textbf{Jacobi identity})$$

for all $a, b, c \in L$. The first condition implies

$$[a, b] = -[b, a] \qquad (\textbf{anticommutativity})$$

and is equivalent to anticommutativity if the characteristic of $F \neq 2$.

A Lie algebra L is **abelian** if $[a, b] = 0$ for all $a, b \in L$.

If A is an algebra, the vector space A together with the product $[\ ,\ ] : A \times A \to A$ defined by $[a, b] = ab - ba$ is an algebra denoted by A^-.

Let L be a Lie algebra. Let I denote the ideal in $T(L)$ (the tensor algebra on the vector space L) generated by $\{a \otimes b - b \otimes a - [a, b] | a, b \in L\}$. The quotient algebra $T(V)/I$ is called the **universal enveloping algebra** of L and is denoted by $U(L)$.

Let V be a vector space with basis X. Define a map $\iota : X \to T(V)^-$ by $\iota : x \mapsto x \in V^{\otimes 1} \subseteq F1 + \sum_{n=1}^{\infty} V^{\otimes n} = T(V)^-$. Let $Fr(X)$ be the Lie subalgebra of $T(V)^-$ generated by $\iota(X)$. $Fr(X)$ is called the **free Lie algebra generated by** X.

Let V be a vector space and let I be the ideal in $T(V)$ generated by $\{a \otimes b - b \otimes a | a, b \in V\}$. The quotient $T(V)/I$ is called the **symmetric algebra** on V and denoted by $S(V)$. The image of $V^{\otimes n}$ in $S(V)$ is denoted by $S^n(V)$. An equivalent construction of this algebra (as a subalgebra, denoted $\bigvee V$, of $T(V)$) is given in Section 14.9.

Let V be a vector space and let I be the ideal in $T(V)$ generated by $\{a \otimes a | a \in V\}$. The quotient $T(V)/I$ is called the **exterior algebra** on V and denoted by $\Lambda(V)$. The image of $a_1 \otimes \ldots \otimes a_l$ is denoted by $a_1 \wedge \ldots \wedge a_l$ and the image of $V^{\otimes n}$ in $\Lambda(V)$ is denoted by $\Lambda^n(V)$. An equivalent construction of this algebra (as a subalgebra, denoted $\bigwedge V$, of $T(V)$) is given in Section 14.9.

Let $\operatorname{End} V$ denote the vector space of all linear transformations from V to V (also denoted $L(V, V)$ elsewhere in this book). Let L be a Lie algebra. If $a \in A$, the map $ad : L \to \operatorname{End} L$ defined by $ad(a) : b \mapsto [a, b]$ for all $b \in L$ is called the **adjoint map**.

Let F be a field of prime characteristic p and let L be a Lie algebra over F. If for every $a \in L$ there is some element $a^{[p]} \in L$ such that $(ad(a))^p = ad(a^{[p]})$, then L is called a **p-Lie algebra**.

Facts:

The following facts (except those with a specific reference) can be found in [Jac62, Chap. 5].

1. [Jac62, p. 6] If A is an associative algebra, then A^- is a Lie algebra. If F is a field of prime characteristic p, then A^- is a p-Lie algebra.
2. Let A be an algebra over F. Then $Der(A)$ is a Lie algebra. If F is a field of prime characteristic p, then $Der(A)$ is a p-Lie algebra.
3. Let V be a vector space. The tensor algebra $T(V)$ has the structure of an associative algebra and $T(V)^-$ is a Lie algebra.
4. Let L be a Lie algebra. A subspace $I \subseteq L$ is an *ideal* of L if $[a, b] \in I$ whenever $a \in A, b \in I$. The quotient space L/I with the product $[a + I, b + I] = [a, b] + I$ is a Lie algebra.
5. *Universal property of* $U(L)$: Let L be a Lie algebra. Define a map $\iota : L \to U(L)$ by $\iota : a \mapsto a \in L^{\otimes 1} \subseteq F1 + \sum_{n=1}^{\infty} L^{\otimes n} = T(L) \to U(L)$. Then ι is a (Lie algebra) homomorphism of L into $U(L)^-$. If A is any associative algebra with unit 1 and ϕ is

a homomorphism of L into A^-, then there is a unique homomorphism $\psi : U(L) \to A$ such that $\psi(1) = 1$ and $\phi = \psi\iota$.

6. *Poincaré–Birkhoff–Witt Theorem:* Let L be a Lie algebra with ordered basis $\{l_i | i \in I\}$. Then $\{l_{i_1} \dots l_{i_k} | k \geq 0, i_1 \leq \dots \leq i_k\}$ is a basis for $U(L)$. Consequently, $\iota : L \to U(L)$ is injective.
7. *Universal property of the free Lie algebra:* If L is any Lie algebra and if $\phi : X \to L$ is any map, there is a unique homomorphism of Lie algebras $\psi : Fr(X) \to L$ such that $\phi = \psi\iota$.
8. *Universal property of* $S(V)$: Let V be a vector space. Define a map $\iota : V \to S(V)$ by $\iota : a \mapsto a \in V^{\otimes 1} \subseteq F1 + \sum_{n=1}^{\infty} V^{\otimes n} \to S(V)$. Let A be a commutative associative algebra and $\phi : V \to A$ be a linear map. Then there is a unique algebra homomorphism $\psi : S(V) \to A$ such that $\phi = \psi\iota$.
9. *Structure of* $S(V)$: Let V be a vector space with ordered basis $B = \{b_i | i \in I\}$. Then $S(V)$ has basis $\{b_{i_1} \dots b_{i_l} | l \geq 0, i_1 \leq \dots \leq i_l\}$. Consequently, $S(V)$ is isomorphic to the algebra of polynomials on B.
10. [Lam01, p. 12] *Structure of* $\Lambda(V)$: Let V be a vector space with ordered basis $B = \{b_i | i \in I\}$. Then $\Lambda(V)$ has basis $\{b_{i_1} \wedge \dots \wedge b_{i_l} | l \geq 0, i_1 < \dots < i_l\}$. Consequently, if V has finite dimension l, then dim $\Lambda(V) = 2^l$.

Examples:

1. $(\operatorname{End} V)^-$ is a Lie algebra, denoted $\mathfrak{gl}(V)$. Similarly, $(F^{n \times n})^-$ is a Lie algebra, denoted $\mathfrak{gl}(n, F)$. These algebras are isomorphic.
2. $sl(n, F) = \{x \in \mathfrak{gl}(n, F) | tr(x) = 0\}$ is a Lie subalgebra, and in fact, a Lie ideal of $\mathfrak{gl}(n, F)$.
3. Let L be a vector space with basis $\{e, f, h\}$. Defining $[e, f] = h, [h, e] = 2e$, and $[h, f] = -2f$ gives L the structure of a Lie algebra. The linear map $L \to sl(2, F)$ defined by $e \mapsto \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, f \mapsto \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix}, h \mapsto \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$ is an isomorphism of Lie algebras.

87.2 Semisimple and Simple Algebras

Definitions:

Let L be a Lie algebra. The subspace spanned by all products $[a, b], a, b \in L$, is a subalgebra of L. It is called the **derived algebra** of L and is denoted by $L^{(1)}$.

Let L be a Lie algebra. For $n \geq 2$, $L^{(n)}$ is defined to be $(L^{(n-1)})^{(1)}$ and is called the **nth-derived algebra** of L.

A Lie algebra L is **solvable** if $L^{(n)} = \{0\}$ for some $n \geq 1$.

Let L be a Lie algebra. The sum of all the solvable ideals of L is the **radical** of L and denoted *Rad*(L). (In Section 86.2, *Rad*(L) is called the *solvable radical* and denoted Solv L.)

A Lie algebra L is **semisimple** if *Rad*$(L) = \{0\}$. N.B. This is standard terminology in the study of Lie algebras, but does *not* always coincide with the definition of semisimple given for nonassociative algebras in Section 86.2; cf. Fact 5 and Example 3.

A Lie algebra L is **simple** if L contains no nonzero proper ideals and $L^{(1)} \neq \{0\}$. (The second condition excludes the one-dimensional algebra.)

Let A, B be Lie algebras. Then the vector space $A \oplus B$ can be given the structure of a Lie algebra, called the **direct sum** of A and B and also denoted $A \oplus B$, by setting $[a_1 + b_1, a_2 + b_2] = [a_1, a_2] + [b_1, b_2]$ for $a_1, a_2 \in A, b_1, b_2 \in B$.

Let L be a finite-dimensional Lie algebra. The **Killing form**, κ_L, is the symmetric bilinear form on L defined by $\kappa_L(a, b) = tr((ad(a))(ad(b)))$.

For V a finite dimensional vector space over an algebraically closed field F and $x \in \operatorname{End} V$, x is **semisimple** if the minimum polynomial of x has no repeated roots.

Let L be a Lie algebra over an algebraically closed field F and $x \in L$. x is **ad-nilpotent** if $ad(x)$ is a nilpotent linear transformation of L and x is **ad-semisimple** if $ad(x)$ is a semisimple linear transformation of L.

Let L be a Lie algebra. A subalgebra $T \subseteq L$ is a **torus** if every element of T is ad-semisimple.

Let T be a torus in L and let $\alpha \in T^*$, the dual of T. Define L_α, the **α-root space** of L by

$$L_\alpha = \{x \in L | [t, x] = \alpha(t)x \ \forall \ t \in T\}.$$

A vector space E over $\mathbb{R}$ with an inner product (i.e., a positive definite symmetric bilinear form)$\langle ., . \rangle$ is a **Euclidean space**.

Let E be a Euclidean space.

For $0 \neq x \in E$ and $y \in E$ set $< y, x > = \frac{2\langle y,x\rangle}{\langle x,x\rangle}$.

For $0 \neq x \in E$ define σ_x, the **reflection** in the hyperplane orthogonal to x, by

$$\sigma_x(y) = y - < y, x > x$$

for all $y \in E$.

A finite subset $R \subseteq E$ that spans E and does not contain 0 is a **root system** in E if the following three conditions are satisfied:

- If $x \in R$, $a \in \mathbb{R}$, and $ax \in R$, then $a = \pm 1$.
- If $x \in R$, then $\sigma_x R = R$
- If $x, y \in R$, then $< x, y > \in \mathbb{Z}$.

Let R be a root system in E. The **rank** of R is dim E.

A root system R is **decomposable** if $R = R_1 \cup R_2$ with $\emptyset \neq R_1, R_2 \subset R$ and $(R_1, R_2) = \{0\}$. If R is not decomposable, it is **indecomposable**.

Let R be a root system in E. The subgroup of $\operatorname{End} E$ generated by $\{\sigma_\alpha | \alpha \in R\}$ is called the **Weyl group** of R.

Let R be a root system in E. A subset $B \subseteq R$ is a **base** for R if B is a basis for E and every $x \in R$ may be written

$$x = \sum_{b \in B} k_b b$$

where all $k_b \geq 0$ or all $k_b \leq 0$.

Let R be a root system in E with base B and let $\alpha \in R$. α is a **positive** root if $\alpha = \sum_{b \in B} k_b b$ where all $k_b \geq 0$. Denote the set of positive roots by R^+.

Let $B = \{b_1, \ldots, b_l\}$ be a base for a root system R. The matrix $\left[< b_i, b_j >\right]$ is called the **Cartan matrix** of R with respect to B.

Facts:

Most of the following facts (except those with a specific reference) can be found in [Hum72, pp. 35–65].

1. The **radical**, $Rad(L)$, is a solvable ideal of L.
2. For V a finite dimensional vector space over an algebraically closed field F, $x \in \operatorname{End} V$ is semisimple if and only if x is similar to a diagonal matrix.
3. [Jac62, p. 69] *Cartan's Criterion for Semisimplicity:* Let L be a finite-dimensional Lie algebra over a field of characteristic 0. Then L is semisimple if and only if κ_L is nondegenerate.
4. [Jac62, p. 74] Let L be a finite-dimensional semisimple Lie algebra over a field of characteristic zero and let $D \in Der(L)$. Then $D = ad(a)$ for some $a \in L$.

5. [Jac62, p. 71] Let L be a finite-dimensional semisimple Lie algebra over a field of characteristic 0. Then L is a direct sum of simple ideals.
6. Let L be a finite-dimensional Lie algebra over an algebraically closed field of characteristic 0. Any torus of L is abelian.
7. Let L be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0. Let T be a maximal torus of dimension l in L and $\Delta = \{\alpha \in T^* | \alpha \neq 0, L_\alpha \neq \{0\}\}$. Then:
   (a) $\dim L_\alpha = 1$ for all $\alpha \in \Delta$.
   (b) $L = T \oplus \sum_{\alpha \in \Delta} L_\alpha$.
   (c) For $\alpha \in \Delta$ there exists $t_\alpha \in T$ such that $\alpha(t) = \kappa_L(t_\alpha, t)$ for all $t \in T$. Then, defining $(\alpha, \beta) = \kappa_L(t_\alpha, t_\beta)$ gives the $\mathbb{R}$ span of Δ the structure of a Euclidean space of dimension l and Δ is a root system of rank l in this space.
   (d) Δ is indecomposable if and only if L is simple.
   (e) Δ spans T^* and so each $w \in W$ acts on T^*.
8. Let R be a root system in E with Weyl group W. Then W is finite and R has a base. Furthermore, if B_1, B_2 are two bases for R, then $B_1 = w(B_2)$ for some $w \in W$. Consequently, when B_1 and B_2 are appropriately ordered, the Cartan matrix of R with respect to B_1 is the same as the Cartan matrix of R with respect to B_2. Thus, we may refer to the Cartan matrix of R.
9. Let L be a semisimple Lie algebra over a field of characteristic 0, let T_1, T_2 be maximal tori in L, and let Δ_1, Δ_2 be the corresponding root systems. Then there is an automorphism $\phi \in Aut(L)$ such that $\phi(T_1) = T_2$. Consequently, when bases for Δ_1 and Δ_2 are appropriately ordered, the Cartan matrix for Δ_1 is the same as the Cartan matrix for Δ_2. Thus, we may refer to the Cartan matrix of L.
10. Let L_1, L_2 be semisimple Lie algebras over an algebraically closed field of characteristic 0. If the Cartan matrices of L_1 and L_2 coincide, then L_1 and L_2 are isomorphic.
11. Let $M = [m_{i,j}]$ be the $l \times l$ Cartan matrix of an indecomposable root system, with base appropriately ordered. Then the diagonal entries of M are all 2 and one of the following occurs.
   (a) M is of type A_l for some $l \geq 1$: $m_{i,j} = -1$ if $|i-j| = 1; m_{i,j} = 0$ if $|i-j| > 1$.
   (b) M is of type B_l for some $l \geq 3$: $m_{l-1,l} = -2; m_{i,j} = -1$ if $|i-j| = 1$ and $(i,j) \neq (l-1, l); m_{i,j} = 0$ if $|i-j| > 1$.
   (c) M is of type C_l for some $l \geq 2$: $m_{l,l-1} = -2; m_{i,j} = -1$ if $|i-j| = 1$ and $(i,j) \neq (l, l-1); m_{i,j} = 0$ if $|i-j| > 1$.
   (d) M is of type D_l for some $l \geq 4$: $m_{i,j} = -1$ if $|i-j| = 1$ and $(i,j) \neq (l-1,l), (l,l-1)$ or if $(i,j) = (l-2,l), (l,l-2); m_{i,j} = 0$ if $|i-j| > 1$ and $(i,j) \neq (l-2,l), (l,l-2)$ or if $(i,j) = (l-1,l), (l,l-1)$.
   (e) M is of type $E_l, l = 6,7,8$: $m_{i,j} = -1$ if $|i-j| = 1$ and $i, j \neq 2$ or if $(i,j) = (1,3)(3,1)(2,4),(4,2)$; $m_{i,j} = 0$ if $|i-j| > 1, (i,j) \neq (1,3)(3,1)(2,4),(4,2)$ or if $|i-j| = 1$ and $i = 2$ or $j = 2$.
   (f) M is of type F_4: $M = \begin{bmatrix} 2 & -1 & 0 & 0 \\ -1 & 2 & -2 & 0 \\ 0 & -1 & 2 & -1 \\ 0 & 0 & -1 & 2 \end{bmatrix}$.
   (g) M is of type G_2: $M = \begin{bmatrix} 2 & -1 \\ -3 & 2 \end{bmatrix}$.
12. Let L be a finite-dimensional simple Lie algebra over an algebraically closed field of characteristic zero. Then L is determined up to isomorphism by its root system

with respect to any maximal torus. The Cartan matrix of the root system is of type $A_l, l \geq 1; B_l, l \geq 3; C_l, l \geq 2; D_l, l \geq 4; E_6, E_7, E_8, F_4$, or G_2.

Examples:

1. The set $\mathbb{R}^3$ with $[\mathbf{u}, \mathbf{v}] = \mathbf{u} \times \mathbf{v}$ (vector cross product) is a three-dimensional simple Lie algebra.
2. The set of all upper triangular complex $n \times n$ matrices is a solvable subalgebra of $\mathfrak{gl}(n, \mathbb{C})$.
3. [Pol69, p. 72] Let $p > 3$ be a prime. The only ideals of $\mathfrak{gl}(p, \mathbb{Z}_p)$ are $0 \subset scal(p, \mathbb{Z}_p) \subset sl(p, \mathbb{Z}_p) \subset \mathfrak{gl}(p, \mathbb{Z}_p)$, where $scal(p, \mathbb{Z}_p)$ is the set of scalar matrices. Thus, the only ideals of $L = \mathfrak{gl}(p, \mathbb{Z}_p)/scal(p, \mathbb{Z}_p)$ are L, $S = sl(p, \mathbb{Z}_p)/scal(p, \mathbb{Z}_p)$ and $\{0\}$. By considering $D = \text{diag}(0, 1, 2, \ldots, p-1)$, we see that $[sl(n, \mathbb{Z}_p), sl(n, \mathbb{Z}_p)] = sl(n, \mathbb{Z}_p)$, so $[S, S] = S$. Thus, S is not solvable and $Rad(L) = 0$. But L cannot be the sum of simple ideals.
4. The following are Cartan matrices of type A_3, B_3, C_3, respectively:

$$\begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -1 & 2 \end{bmatrix}, \quad \begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & -2 \\ 0 & -1 & 2 \end{bmatrix}, \quad \begin{bmatrix} 2 & -1 & 0 \\ -1 & 2 & -1 \\ 0 & -2 & 2 \end{bmatrix}.$$

5. If $n > 1$ and if n is not a multiple of the characteristic of F, let $L = sl(n, F)$. Then L is a simple Lie algebra of dimension $n^2 - 1$. If T denotes the set of diagonal matrices in $sl(n, F)$ and if $\epsilon_i \in T^*$ is defined by $\epsilon_i(\text{diag}(d_1, \ldots, d_n)) = d_i$, then T is a maximal torus in $sl(n, F)$, Δ, the set of roots of $sl(n, F)$ with respect to T, is $\{\epsilon_i - \epsilon_j | i \neq j\}$, and the root space $L_{\epsilon_i - \epsilon_j} = FE_{i,j}$. In addition, $\{\epsilon_i - \epsilon_{i+1} | 1 \leq i \leq n-1\}$ is a base for Δ and so the Cartan matrix of $sl(n, F)$ is of type A_{n-1}.
6. Let $(.,.)$ be the symmetric bilinear form on F^{2l+1} with matrix $\begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & I_l \\ 0 & I_l & 0 \end{bmatrix}$. Then $L = \{x \in \mathfrak{gl}(2l+1, F) | (xu, v) = -(u, xv) \ \forall \ u, v \in F^{2l+1}\}$ is a Lie subalgebra of $\mathfrak{gl}(2l+1, F)$, denoted by $o(2l+1, F)$. If the characteristic of F is not 2, it is a simple algebra of dimension $2l^2 + l$. Let T denote the set of diagonal matrices in $o(2l+1, F)$. If $\epsilon_i \in T^*$ is defined by $\epsilon_i(\text{diag}(d_1, \ldots, d_{2l+1})) = d_i$, and if $\nu_i = \epsilon_{i+1}$ for $1 \leq i \leq l$, then T is a maximal torus in $o(2l+1, F)$; Δ, the set of roots of $o(2l+1, F)$ with respect to T, is $\{\pm\nu_i | 1 \leq i \leq l\} \cup \{\pm\nu_i \pm \nu_j | 1 \leq i \neq j \leq l\}$, and, for $1 \leq i \neq j \leq l$, $L_{\nu_i} = F(E_{1,l+i+1} - E_{i+1,1}), L_{-\nu_i} = F(E_{1,i+1} - E_{l+i+1,1}), L_{\nu_i - \nu_j} = F(E_{i+1,j+1} - E_{l+j+1,l+i+1}), L_{\nu_i + \nu_j} = F(E_{i+1,l+j+1} - E_{j+1,l+i+1}), L_{-\nu_i - \nu_j} = F(E_{l+i+1,j+1} - E_{l+j+1,i+1})$. In addition, $\{\nu_i - \nu_{i+1} | 1 \leq i \leq l-1\} \cup \{\nu_l\}$ is a base for Δ, and so the Cartan matrix of $o(2l+1, F)$ is of type B_l.
7. Let $(.,.)$ be the skew-symmetric bilinear form on F^{2l} with matrix $\begin{bmatrix} 0 & I_l \\ -I_l & 0 \end{bmatrix}$. Then $L = \{x \in \mathfrak{gl}(2l, F) | (xu, v) = -(u, xv) \ \forall \ u, v \in F^{2l}\}$ is a Lie subalgebra of $\mathfrak{gl}(2l, F)$, denoted by $sp(2l, F)$. If the characteristic of F is not 2, it is a simple algebra of dimension $2l^2 + l$. Let T denote the set of diagonal matrices in $sp(2l, F)$. If $\epsilon_i \in T^*$ is defined by $\epsilon_i(\text{diag}(d_1, \ldots, d_{2l})) = d_i$, and if $\mu_i = \epsilon_i$ for $1 \leq i \leq l$, then T is a maximal torus in $sp(2l, F)$, Δ, the set of roots of $sp(2l, F)$ with respect to T, is $\{\pm 2\mu_i | 1 \leq i \leq l\} \cup \{\pm\mu_i \pm \mu_j | i \neq j\}$, and, for $1 \leq i \leq l$, $L_{2\mu_i} = FE_{i,l+i}$, $L_{-2\mu_i} = FE_{l+i,i}$, $L_{\mu_i - \mu_j} = F(E_{i,j} - E_{l+j,l+i})$, $L_{\mu_i + \mu_j} = F(E_{i,l+j} + E_{j,l+i})$, $L_{-\mu_i - \mu_j} = F(E_{l+i,j} + E_{l+j,i})$. In addition, $\{\mu_i - \mu_{i+1} | 1 \leq i \leq l-1\} \cup \{2\mu_l\}$ is a base for Δ, and so the Cartan matrix of $sp(2l, F)$ is of type C_l.
8. Let $(.,.)$ be the symmetric bilinear form on F^{2l} with matrix $\begin{bmatrix} 0 & I_l \\ I_l & 0 \end{bmatrix}$. Then $L = \{x \in \mathfrak{gl}(2l, F) | (xu, v) = -(u, xv) \ \forall \ u, v \in F^{2l}\}$ is a Lie subalgebra of $\mathfrak{gl}(2l, F)$, denoted by $o(2l, F)$. If the characteristic of F is not 2, it is a simple algebra of dimension $2l^2 - l$. Let T denote

the set of diagonal matrices in $o(2l, F)$. If $\epsilon_i \in T^*$ is defined by $\epsilon_i(\text{diag}(d_1, \ldots, d_{2l})) = d_i$, and if $\nu_i = \epsilon_i$ for $1 \leq i \leq l$, then T is a maximal torus in $o(2l, F)$, Δ, the set of roots of $o(2l, F)$ with respect to T, is $\{\pm\nu_i \pm \nu_j | 1 \leq i \neq j \leq l\}$, and, for $1 \leq i \neq j \leq l$, $L_{\nu_i - \nu_j} = F(E_{i,j} - E_{l+j,l+i})$, $L_{\nu_i+\nu_j} = F(E_{i,l+j} - E_{j,l+i})$, $L_{-\nu_i-\nu_j} = F(E_{l+i,j} - E_{l+j,i})$. In addition, $\{\nu_i - \nu_{i+1} | 1 \leq i \leq l-1\} \cup \{\nu_{l-1} + \nu_l\}$ is a base for Δ, and so the Cartan matrix of $o(2l, F)$ is of type D_l.

9. Let V be a vector space of dimension $n \geq 1$ over a field of characteristic 0. Let $W(n) = Der(S(V))$. Then $W(n)$ is an infinite-dimensional simple Lie algebra.
10. Let F be a field of characteristic $p > 0$. Let V be a vector space of dimension $n \geq 1$ with basis $\{x_1, \ldots, x_n\}$. Let I denote the ideal $< x_1^p, \ldots, x_n^p > \subseteq S(V)$, $B(n : \mathbf{1})$ denote $S(V)/I$, and $W(n : \mathbf{1}) = Der(B(n : \mathbf{1}))$. Then $W(n : \mathbf{1})$ is a p-Lie algebra of dimension np^n. It is a simple Lie algebra unless $p = 2$ and $n = 1$.

87.3 Modules

Definitions:

Let A be an associative algebra and V be a vector space over F. A **representation** of A on V is a homomorphism $\phi : A \to \text{End}\, V$.

Let L be a Lie algebra and V be a vector space over F. A **representation** of L on V is a homomorphism $\phi : L \to \mathfrak{gl}(V)$.

Let B be an associative algebra or a Lie algebra. A representation $\phi : B \to \mathfrak{gl}(V)$ is **reducible** if there is some nonzero proper subspace $W \subset V$ such that $\phi(x)(W) \subseteq W$ for all $x \in B$. If ϕ is not reducible, it is **irreducible**.

Let L be a Lie algebra and M be a vector space. M is an **L-module** if there is a linear map $L \otimes M \to M, a \otimes m \mapsto am$ such that $[a, b]m = a(bm) - b(am)$ for all $a, b \in L, m \in M$.

Let M be an L-module. A subspace $N \subseteq M$ is a **submodule** of M if $LN \subseteq N$.

Let M be an L-module. M is **reducible** if M contains a nonzero proper submodule. If M is not reducible it is **irreducible**. If M is a direct sum of irreducible submodules, it is **completely reducible**.

Let M be an L-module and X be a subset of M. The submodule of M **generated by** X is the smallest submodule of M containing X.

Let L be a Lie algebra and M, N be L-modules. A linear transformation $\phi : M \to N$ is a **homomorphism** of L-modules if $\phi(xm) = x\phi(m)$ for all $x \in L, m \in M$. The set of all L-module homomorphisms from M to N is denoted $Hom(M, N)$.

Let L be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0. Let T be a maximal torus in L and M be an L-module. For $\lambda \in T^*$ define M_λ, the **λ-weight space** of M, to be $\{m \in M | tm = \lambda(t)m \forall t \in T\}$.

Let L be a finite-dimensional simple Lie algebra over an algebraically closed field of characteristic 0. Let T be a maximal torus, Δ the corresponding root system, B a base for Δ, and Δ^+ the corresponding set of positive roots. Let M be an L-module and $\lambda \in T^*$. An element $0 \neq m \in M_\lambda$ is a **highest weight vector of weight** λ if $L_\alpha m = 0$ for all $\alpha \in \Delta^+$.

Facts:

Unless specified otherwise, V denotes a vector space over a field F.

The following facts may be found in [Hum72, Sect. 6].

1. Let L be a Lie algebra and $\phi : L \to \mathfrak{gl}(V)$ be a representation of L on V. Then V may be given the structure of an L-module by setting $xv = \phi(x)(v)$ for all $x \in L, v \in V$. Conversely, if M is an L-module, then the map $\phi : L \to \mathfrak{gl}(M)$ defined by $\phi(x)(m) =$

xm is a representation of L on M. A representation ϕ is irreducible if and only if the corresponding module is.
2. Let ϕ be a representation of a Lie algebra L on V. Then, by the universal property of the universal enveloping algebra, ϕ extends to a representation of $U(L)$ on V. Conversely, every representation of $U(L)$ on V restricts to a representation of L on V. A representation ϕ of $U(L)$ on V is irreducible if and only if its restriction to L is.
3. Let L be a Lie algebra, M be an L-module, and $N \subseteq M$ be a submodule. Then the quotient space M/N may be given the structure of an L-module by setting $x(m+N) = xm + N$ for all $x \in L, m \in M$.
4. Let L be a Lie algebra and M, N be L-modules. Then the vector space $M \oplus N$ may be given the structure of an L-module by setting $x(m+n) = xm + xn$ for all $x \in L, m \in M, n \in N$.
5. Let L be a Lie algebra and M, N be L-modules. Then the vector space $M \otimes N$ may be given the structure of an L-module by setting $x(m \otimes n) = xm \otimes n + m \otimes xn$ for all $x \in L, m \in M, n \in N$.
6. Let L be a Lie algebra and M, N be L-modules. Then $Hom(M, N)$ may be given the structure of an L-module by setting $(x\phi)(m) = x\phi(m) - \phi(xm)$ for all $x \in L, m \in M$.
7. Let L be a Lie algebra and V be an L-module. Then $T(V)$ is an L-module and the ideals occurring in the definitions of $S(V)$ and $\Lambda(V)$ are submodules. Hence, $S(V)$ and $\Lambda(V)$ are L-modules. Furthermore, each $S^n(V)$ is a submodule of $S(V)$ and each $\Lambda^n(V)$ is a submodule of $\Lambda(V)$.
8. [Jac62, p. 79] *Weyl's Theorem:* Let L be a finite-dimensional semisimple Lie algebra over a field of characteristic zero and let M be a finite-dimensional L-module. Then M is completely reducible.
9. [Hum72, pp. 107–114] Let L be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0 and M be a finite-dimensional L-module. Let T be a maximal torus in L, Δ be the corresponding root system, $B = \{\alpha_1, \ldots, \alpha_l\}$ a base for Δ, and Δ^+ be the corresponding set of positive roots. Then:
   (a) $M = \sum_{\lambda \in T^*} M_\lambda$.
   (b) M contains a highest weight vector of weight λ for some $\lambda \in T^*$ and setting $h_i = \frac{2t_{\alpha_i}}{(\alpha_i, \alpha_i)}$ for $1 \leq i \leq l$, we have $\lambda(h_i) \geq 0, \lambda(h_i) \in \mathbb{Z}$ for $1 \leq i \leq l$.
   (c) If M is irreducible and m_1, m_2 are highest weight vectors corresponding to $\lambda_1, \lambda_2 \in T^*$, then $\lambda_1 = \lambda_2$ and $Fm_1 = Fm_2$.
   (d) If M, N are irreducible finite-dimensional L-modules containing highest weight vectors corresponding to the same $\lambda \in T^*$, then M and N are isomorphic.
   (e) Let $\lambda \in T^*$ satisfy $\lambda(h_i) \in \mathbb{Z}, \lambda(h_i) \geq 0$ for $1 \leq i \leq l$. Then there exists a finite-dimensional L-module with highest weight λ.

Examples:

1. Let V be a vector space of dimension $n > 1$. Then V is a $\mathfrak{gl}(V)$-module and, hence, a $\mathfrak{gl}(n, F)$-module. Therefore, for each $k > 0$, $S^k(V)$ and $\Lambda^k(V)$ are modules for $\mathfrak{gl}(V)$ and, thus, modules for any subalgebra of $\mathfrak{gl}(n, F)$.
2. Let V be a vector space with basis $\{x, y\}$. Let $\{e, f, h\}$ be a basis for $sl(2, F)$ with $[e, f] = h, [h, e] = 2e, [h, f] = -2f$. The linear map $sl(2, F) \to Der(F[x, y])$ defined by $e \mapsto \frac{x\partial}{\partial y}, f \mapsto \frac{y\partial}{\partial x}, h \mapsto \frac{x\partial}{\partial x} - \frac{y\partial}{\partial y}$ is an isomorphism of $sl(2, F)$ into $Der(F[x, y])$. Consequently, $F[x, y] = S(V)$ is an $sl(2, F)$-module and each $S^n(V)$ is an $sl(2, F)$ submodule. $S^n(V)$ has basis $\{x^n, x^{n-1}y, \ldots, y^n\}$ and so is an $(n+1)$-dimensional $sl(2, F)$-module. It is irreducible.

87.4 Graded Algebras and Modules

Definitions:

Let V be a vector space and A be an additive abelian group. For each $\alpha \in A$, let V_α be a subspace of V. If $V = \oplus_{\alpha \in A} V_\alpha$, then V is an **A-graded vector space**.

Let B be an algebra and an A-graded vector space. B is an **A-graded algebra** if $B_\alpha B_\beta \subseteq B_{\alpha+\beta}$ for all $\alpha, \beta \in A$.

Let B be an A-graded associative algebra or an A-graded Lie algebra. Let M be a B-module and an A-graded vector space. M is an **A-graded module** for B if $B_\alpha M_\beta \subseteq M_{\alpha+\beta}$ for all $\alpha, \beta \in A$.

Let V be an A-graded vector space. V has **graded dimension** if $\dim(V_\alpha) < \infty$ for all $\alpha \in A$. In this case, we define the **graded dimension** of V to be the formal sum

$$\mathit{gr\ dim}(V) = \sum_{\alpha \in A} \dim(V_\alpha) t^\alpha.$$

The graded dimension of V is sometimes called the **character** of V.

Facts:

1. [FLM88, Sect. 1.10] Let V, W be A-graded vector spaces with graded dimensions. Then $V \oplus W$ is a graded vector space with graded dimension and $\mathit{gr\ dim}(V \oplus W) = \mathit{gr\ dim}(V) + \mathit{gr\ dim}(W)$. If W is a subspace of V and $W_\alpha \subseteq V_\alpha$ for all $\alpha \in A$, then the quotient space V/W has graded dimension and $\mathit{gr\ dim}(V/W) = \mathit{gr\ dim}(V) - \mathit{gr\ dim}(W)$. If $\{(\alpha, \beta) \in A \times A | V_\alpha, W_\beta \neq \{0\}, \alpha + \beta = \gamma\}$ is finite for all $\gamma \in A$, then $V \otimes W$ is a graded vector space with graded dimension, where $(V \otimes W)_\gamma = \sum_{\alpha+\beta=\gamma} V_\alpha \otimes W_\beta$ and $\mathit{gr\ dim}(V \otimes W) = (\mathit{gr\ dim}(V))(\mathit{gr\ dim}(W))$ (where we set $t^\alpha t^\beta = t^{\alpha+\beta}$).
2. [Bou72, p. 36] Let V be a vector space with basis X. Setting $Fr(X)_i = Fr(X) \cap V^{\otimes i}$ gives $Fr(X)$ the structure of a graded Lie algebra. If $|X| = l$ is finite, $Fr(X)$ has graded dimension and $\mathit{gr\ dim}(Fr(X)) = \sum_{n>0} \frac{1}{n} (\sum_{d|n} \mu(d) l^{\frac{n}{d}}) t^n$, where μ is the Möbius function (i.e., $\mu(p_1 \dots p_r) = (-1)^r$ if $p_1, \dots, p_r$ are distinct primes and $\mu(n) = 0$ if $p^2 | n$ for some prime p).
3. [Jac62, Sect. VIII.3] Let L be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0, T be a maximal torus in L, Δ be the corresponding root system, W be the Weyl group, Δ^+ be the set of positive roots with respect to some base, and M be a finite-dimensional L-module. Then:
   (a) Let $\mathbb{Z}\Delta$ denote the additive subgroup of T^* generated by Δ. Then the root space decomposition $L = T + \sum_{\alpha \in \Delta} L_\alpha$ gives L the structure of a $\mathbb{Z}\Delta$-graded Lie algebra. Here $L_0 = T$.

   (b) The weight space decomposition $M = \sum_{\alpha \in T^*} M_\alpha$ gives M the structure of a graded module with graded dimension.

   (c) *Weyl character formula:* Assume M is irreducible with highest weight λ. Let $\delta = \frac{1}{2} \sum_{\alpha \in \Delta^+} \alpha$. Then

$$\mathit{gr\ dim}(M) = \left(\sum_{w \in W} (\det(w) t^{w(\lambda+\delta)}) \right) \Bigg/ \left(\sum_{w \in W} (\det(w) t^{w\delta}) \right).$$

Examples:

1. Setting $T(V)_i = V^{\otimes i}$ gives $T(V)$ the structure of a $\mathbb{Z}$-graded algebra. If V has finite dimension l, then $T(V)$ has graded dimension and $gr\ dim(T(V)) = (1 - lt)^{-1}$.
2. Setting $S(V)_i = S^i(V)$ gives $S(V)$ the structure of a $\mathbb{Z}$-graded algebra. If V has finite dimension l, then $S(V)$ has graded dimension and $gr\ dim(S(V)) = (1 - t)^{-l}$.
3. Setting $\Lambda(V)_i = \Lambda^i(V)$ gives $\Lambda(V)$ the structure of a $\mathbb{Z}$-graded algebra. If V has finite dimension l, then $\Lambda(V)$ has graded dimension and $gr\ dim(\Lambda(V)) = (1 + t)^l$.
4. Let L be a finite-dimensional semisimple Lie algebra over an algebraically closed field of characteristic 0, T be a maximal torus in L, Δ be the corresponding root system, and $B = \{\alpha_1, \ldots, \alpha_l\}$ be a base. For $1 \leq i \leq l$ define λ_i by $\lambda_i(\frac{2t_{\alpha_j}}{(\alpha_j,\alpha_j)}) = \delta_{i,j}$. Then:
   (a) If $L = sl(V)$, where V is an $l + 1$-dimensional vector space and the base for Δ is as described in Example 87.2.5, then $\Lambda^i(V)$ is the irreducible $sl(V)$-module of highest weight λ_i for $1 \leq i \leq l$.
   (b) If $L = o(V)$, where V is a $2l + 1$-dimensional vector space and the base for Δ is as described in Example 87.2.6, then $\Lambda^i(V)$ is the irreducible $o(V)$-module of highest weight λ_i for $1 \leq i \leq l - 1$.
   (c) If $L = o(V)$, where V is a $2l$-dimensional vector space and the base for Δ is as described in Example 87.2.8, then $\Lambda^i(V)$ is the irreducible $o(V)$-module of highest weight λ_i for $1 \leq i \leq l - 2$.

MATLAB® is generally recognized as the leading software for scientific computation. It was originally developed in the 1970s by Cleve Moler as an interactive Matrix Laboratory with matrix routines based on the algorithms in the LINPACK and EISPACK software libraries. In the original 1978 version everything in MATLAB® was done with matrices, even the graphics. MATLAB® has continued to grow and expand from the classic 1978 Fortran version to the current version, R2013a, which was released in March 2013. Each new release has included significant improvements. The graphics capabilities were greatly enhanced with the introduction of Handle Graphics and Graphical User Interfaces in version 4 (1992). A sparse matrix package was also included in version 4. Over the years dozens of toolboxes (application libraries of specialized MATLAB® files) have been added in areas such as signal processing, statistics, optimization, symbolic math, splines, and image processing. MATLAB®'s matrix computations are now based on the LAPACK software library.

88.1 Matrices, Submatrices, and Multidimensional Arrays

Facts:

1. The basic data elements that MATLAB® uses are matrices. Matrices can be entered into a MATLAB® session using square brackets.
2. If A and B are matrices with the same number of rows, then one can append the columns of B to the matrix A and form an augmented matrix C by setting `C = [A, B]`. If E is a matrix with the same number of columns as A, then one can append the rows of E to A and form an augmented matrix F by setting `F = [A; E]`.

3. Row vectors of evenly spaced entries can be generated using MATLAB®'s : operator.
4. A submatrix of a matrix A is specified by $\mathsf{A(u,v)}$ where u and v are vectors that specify the row and column indices of the submatrix.
5. MATLAB® arrays can have more than two dimensions.

Commands:

1. The number of rows and columns of a matrix can be determined using MATLAB®'s `size` command.
2. The command `length(x)` can be used to determine the number of entries in a vector `x`. The `length` command is equivalent to the command `max(size(x))`.
3. MATLAB®'s `cat` command can be used to concatenate two or more matrices along a single dimension and it can also be used to create multidimensional arrays. If two matrices `A` and `B` have the same number of columns, then the command `cat(1, A, B)` produces the same matrix as the command `[A; B]`. If the matrices B and C have the same number of rows, the command `cat(2, B, C)` produces the same matrix as the command `[B, C]`. The `cat` command can be used with more than two matrices as arguments. For example, the command `cat(2, A, B, C, D)` generates the same matrix as the command `[A, B, C, D]`. If `A1`, `A2`, ..., `Ak` are $m \times n$ matrices, the command `S = cat(3, A1, A2, ..., Ak)` will generate an $m \times n \times k$ array `S`.

Examples:

1. The matrix

$$A = \begin{bmatrix} 1 & 2 & 4 & 3 \\ 3 & 5 & 7 & 2 \\ 2 & 4 & 1 & 1 \end{bmatrix}$$

is generated using the command

```
A =  [1  2  4  3
      3  5  7  2
      2  4  1  1]
```

Alternatively one could generate the matrix on a single line using semicolons to designate the ends of the rows

```
A = [ 1  2  4  3; 3  5  7  2; 2  4  1  1]
```

The command `size(A)` will return the vector $(3, 4)$ as the answer. The command `size(A,1)` will return the value 3, the number of rows of A, and the command `size(A,2)` will return the value 4, the number of columns of A.

2. The command

```
x = 3 : 7
```

will generate the vector $\mathbf{x} = [3,\ 4,\ 5,\ 6,\ 7]$. To change the step size to $\frac{1}{2}$, set

```
z = 3 : 0.5 : 7
```

This will generate the vector $\mathbf{z} = [3,\ 3.5,\ 4,\ 4.5,\ 5,\ 5.5,\ 6,\ 6.5,\ 7]$. The MATLAB® commands `length(x)` and `length(z)` will generate the answers 5 and 9, respectively.

3. If A is the matrix in Example 1, then the command `A(2,:)` will generate the second row vector of A and the command `A(:,3)` will generate the third column vector of A. The submatrix of elements that are in the first two rows and last two columns is given by `A(1:2, 3:4)`. Actually

there is no need to use adjacent rows or columns. The command $\mathsf{C} = \mathsf{A}([1\ \ 3],[1\ \ 3\ \ 4])$ will generate the submatrix

$$C = \begin{bmatrix} 1 & 4 & 3 \\ 2 & 1 & 1 \end{bmatrix}$$

4. The command

$$\mathsf{S} = \mathsf{cat}(3,\ [5\ 1\ 2;\ 3\ 2\ 1],\ [1\ 2\ 3;\ 4\ 5\ 6])$$

will produce a $2 \times 3 \times 2$ array S with

$$\begin{aligned} \mathsf{S}(:,:,1) &= \\ & \quad \begin{matrix} 5 & 1 & 2 \\ 3 & 2 & 1 \end{matrix} \end{aligned}$$

and

$$\begin{aligned} \mathsf{S}(:,:,2) &= \\ & \quad \begin{matrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{matrix} \end{aligned}$$

88.2 Matrix Arithmetic

The six basic MATLAB® operators for doing matrix arithmetic are: $+$, $-$, $*$, ^, \, and /. The matrix left and right divide operators, \ and /, are described in Section 88.5. These same operators are also used for doing scalar arithmetic.

Facts:

1. If A and B are matrices with the same dimensions, then their sum and difference are computed using the commands: $\mathsf{A} + \mathsf{B}$ and $\mathsf{A} - \mathsf{B}$.
2. If B and C are matrices and the multiplication BC is possible, then the product $E = BC$ is computed using the command

$$\mathsf{E} = \mathsf{B} * \mathsf{C}$$

3. The kth power of a square matrix A is computed with the command $\mathsf{A\hat{\ }k}$.
4. Scalars can be either real or complex numbers. A complex number such as $3 + 4i$ is entered in MATLAB® as $3 + 4\mathsf{i}$. It can also be entered as $3 + 4 * \mathsf{sqrt}(-1)$ or by using the command $\mathsf{complex}(3, 4)$. If i is used as a variable and assigned a value, say $i = 5$, then MATLAB® will assign the expression $3 + 4 * \mathsf{i}$ the value 23; however, the expression $3 + 4\mathsf{i}$ will still represent the complex number $3 + 4i$. In the case that i is used as a variable and assigned a numerical value, one should be careful to enter a complex number of the form $a + i$ (where a is real) as $\mathsf{a} + 1\mathsf{i}$.
5. MATLAB® will perform arithmetic operations elementwise when the operator is preceded by a period in the MATLAB® command.
6. The conjugate transpose of a matrix B is computed using the command B'. If the matrix B is real, then B' will be equal to the transpose of B. If B has complex entries, then one can take its transpose without conjugating using the command $\mathsf{B.}'$.

Commands:

1. The inverse of a nonsingular matrix C is computed using the command $\mathsf{inv}(\mathsf{C})$.
2. The determinant of a square matrix A is computed using the command $\mathsf{det}(\mathsf{A})$.

Examples:

1. If

$$A = \begin{bmatrix} 1 & 2 \\ 3 & 4 \end{bmatrix} \qquad \text{and} \qquad B = \begin{bmatrix} 5 & 1 \\ 2 & 3 \end{bmatrix}$$

the commands `A*B` and `A.*B` will generate the matrices

$$\begin{bmatrix} 9 & 7 \\ 23 & 15 \end{bmatrix}, \qquad \begin{bmatrix} 5 & 2 \\ 6 & 12 \end{bmatrix}$$

88.3 Built-in MATLAB® Functions

The `inv` and `det` commands are examples of built-in MATLAB® functions. Both functions have a single input and a single output. Thus, the command `d = det(A)` has the matrix A as its input argument and the scalar d as its output argument. A MATLAB® function may have many input and output arguments. When a command of the form

$$[A_1, \ldots, A_k] = \mathsf{fname}(B_1, \ldots, B_n) \tag{88.1}$$

is used to call a function `fname` with input arguments $B_1, \ldots, B_n$, MATLAB® will execute the function routine and return the values of the output arguments $A_1, \ldots, A_k$.

Facts:

1. The number of allowable input and output arguments for a MATLAB® function is defined by a `function` statement in the MATLAB® file that defines the function. (See Section 88.8.) The function may require some or all of its input arguments. A MATLAB® command of the form (88.1) may be used with less than k output arguments. The MATLAB® help facility describes the various input and output options for each of the MATLAB® commands.

Examples:

1. The MATLAB® function `pi` is used to generate the number π. This function is used with no input arguments.
2. The MATLAB® command `eps` can be used with either 0 or 1 input arguments. With 1 input argument the command `d = eps(x)` returns the positive distance from $|x|$ to the next larger in magnitude floating point number of the same precision as x. With no input arguments the command `eps` returns 2^{-52}, the value of `eps`(1.0) the standard unit roundoff for double precision floating point arithmetic. By default the value of `eps` returned will be in the form 2.2204e − 016, the MATLAB® format short decimal representation of 2^{-52}.
3. The MATLAB® function `kron` has two input arguments. If A and B are matrices, then the command `kron(A,B)` computes the Kronecker product of A and B. Thus, if A = [1, 2; 3, 4] and B = [1, 1; 1, 1], then the command `K = kron(A, B)` produces the matrix

```
K =

     1     1     2     2
     1     1     2     2
     3     3     4     4
     3     3     4     4
```

and the command $\mathsf{L} = \mathsf{kron}(\mathsf{B}, \mathsf{A})$ produces the matrix

```
L  =
       1  2  1  2
       3  4  3  4
       1  2  1  2
       3  4  3  4
```

4. One can compute the QZ factorization (see Section 88.6) for the generalized eigenvalue problem using a command

   $$[\,\mathsf{E}, \mathsf{F}, \mathsf{Q}, \mathsf{Z}\,] = \mathsf{qz}(\mathsf{A}, \mathsf{B})$$

   with two input arguments and four outputs. The input arguments are square matrices A and B and the outputs are quasitriangular matrices E and F and unitary matrices Q and Z such that

   $$QAZ = E \quad \text{and} \quad QBZ = F$$

   The command

   $$[\mathsf{E}, \mathsf{F}, \mathsf{Q}, \mathsf{Z}, \mathsf{V}, \mathsf{W}] = \mathsf{qz}(\mathsf{A}, \mathsf{B})$$

   will also compute matrices V and W of generalized eigenvectors.

88.4 Special Matrices

The ELMAT directory of MATLAB® contains a collection of MATLAB® functions for generating special types of matrices.

Commands:

1. The following table lists commands for generating various types of special matrices.

Matrix	**Command Syntax**	**Description**
eye	`eye(n)`	Identity matrix
ones	`ones(n)` or `ones(m, n)`	Matrix whose entries are all equal to 1
zeros	`zeros(n)` or `zeros(m, n)`	Matrix whose entries are all equal to 0
rand	`rand(n)` or `rand(m, n)`	Random matrix
compan	`compan(p)`	Companion matrix
hadamard	`hadamard(n)`	Hadamard matrix
gallery	`gallery(matname, p1, p2,...)`	A large collection of special test matrices
hankel	`hankel(c)` or `hankel(c,r)`	Hankel matrix
hilb	`hilb(n)`	Hilbert matrix
invhilb	`invhilb(n)`	Inverse Hilbert matrix
magic	`magic(n)`	Magic square
pascal	`pascal(n)`	Pascal matrix
rosser	`rosser`	Test matrix for eigenvalue solvers
toeplitz	`toeplitz(c)` or `toeplitz(c,r)`	Toeplitz matrix
vander	`vander(x)`	Vandermonde matrix
wilkinson	`wilkinson(n)`	Wilkinson's eigenvalue test matrix

2. The command `gallery` can be used to access a large collection of test matrices developed by N. J. Higham. Enter `help gallery` to obtain a list of all classes of gallery test matrices.

Examples:

1. The command `rand(n)` will generate an $n \times n$ matrix whose entries are random numbers that are uniformly distributed in the interval $(0, 1)$. The command may be used with two input arguments to generate nonsquare matrices. For example, the command `rand(3,2)` will generate a random 3×2 matrix. The command `rand` when used by itself with no input arguments will generate a single random number between 0 and 1.
2. The command

   ```
   A = [eye(2), ones(2,3); zeros(2), 2 * ones(2,3)]
   ```

   will generate the matrix

   ```
   A =
        1  0  1  1  1
        0  1  1  1  1
        0  0  2  2  2
        0  0  2  2  2
   ```

3. The command `toeplitz(c)` will generate a symmetric toeplitz matrix whose first column is the vector `c`. Thus, the command

   ```
   toeplitz([1; 2; 3])
   ```

   will generate

   ```
   ans =
        1  2  3
        2  1  2
        3  2  1
   ```

   Note that in this case since the `toeplitz` command was used with no output argument, the computed value of the command `toeplitz(c)` was assigned to the temporary variable `ans`. Further computations may end up overwriting the value of `ans`. To keep the matrix for further use in the MATLAB® session it is advisable to include an output argument in the calling statement.

   For a nonsymmetric Toeplitz matrix it is necessary to include a second input argument `r` to define the first row of the matrix. If $\mathsf{r}(1) \neq \mathsf{c}(1)$, the value of $c(1)$ is used for the main diagonal. Thus, commands

   ```
   c = [1; 2; 3],    r = [9, 5, 7],    T = toeplitz(c, r)
   ```

   will generate

   ```
   T =
        1  5  7
        2  1  5
        3  2  1
   ```

   The Toeplitz matrix generated is stored using the variable `T`.
4. One of the classes of gallery test matrices are circulant matrices. These are generated using the MATLAB® function `circul`. To see how to use this function, enter the command

   ```
   help private\circul
   ```

   The help information will tell you that the `circul` function requires an input vector `v` and that the command

   ```
   C = gallery('circul', v)
   ```

will generate a circulant matrix whose first row is v. Thus, the command

$$\mathsf{C} = \mathsf{gallery}('\mathsf{circul}', [4,5,6])$$

will generate the matrix

```
C  =
        4   5   6
        6   4   5
        5   6   4
```

88.5 Linear Systems and Least Squares

The simplest way to solve a linear system in MATLAB® is to use the matrix left divide operator.

Facts:

1. The symbol \ represents MATLAB®'s matrix left divide operator. One can compute the solution to a linear system $A\mathbf{x} = \mathbf{b}$ by setting

   $$\mathsf{x} = \mathsf{A} \backslash \mathsf{b}$$

   If A is an $n \times n$ matrix, then MATLAB® will compute the solution using Gaussian elimination with partial pivoting. A warning message is given when the matrix is badly scaled or nearly singular. If the coefficient matrix is nonsquare, then MATLAB® will return a least squares solution to the system that is essentially equivalent to computing $A^{\dagger}\mathbf{b}$ (where $A^{\dagger}$ denotes the pseudoinverse of A). In this case, MATLAB® estimates the numerical rank of the coefficient matrix using a QR decomposition and gives a warning when the matrix is numerically rank deficient.
   If A is an $m \times n$ matrix and B is $m \times k$, then the command

   $$\mathsf{C} = \mathsf{A} \backslash \mathsf{B}$$

   will produce an $n \times k$ matrix whose column vectors satisfy

   $$\mathbf{c}_j = A \backslash \mathbf{b}_j \quad j = 1, \ldots, k$$

2. The symbol / represents MATLAB®'s matrix right divide operator. It is defined by

   $$\mathsf{B}/\mathsf{A} = (\mathsf{A}' \backslash \mathsf{B}')'$$

   In the case that A is nonsingular, the computation B/A is essentially the same as computing BA^{-1}; however, the computation is carried out without actually computing A^{-1}.

Commands:

The following table lists some of the main MATLAB® commands that are useful for linear systems.

Function	**Command Syntax**	**Description**
rref	U = rref(A)	Reduced row echelon form of a matrix
lu	[L , U] = lu(A)	LU factorization
linsolve	x = linsolve(A , b , opts)	Efficient solver for structured linear systems
chol	R = chol(A)	The Cholesky factorization of a matrix
norm	p = norm(X)	The norm of a matrix or a vector
null	U = null(A)	Basis for the null space of a matrix
null	R = null(A, 'r')	Basis for null space rational form
orth	Q = orth(A)	Orthonormal basis for the column space of a matrix
rank	r = rank(A)	The numerical rank of a matrix
cond	c = cond(A)	The 2-norm condition number for solving linear systems
rcond	c = rcond(A)	Reciprocal of approximate 1-norm condition number
qr	[Q , R] = qr(A)	QR factorization
svd	s = svd(A)	The singular values of a matrix
svd	[U , S , V] = svd(A)	The singular value decomposition
pinv	B = pinv(A)	The pseudoinverse of a matrix

Examples:

1. The null command can be used to produce an orthonormal basis for the nullspace of a matrix. It can also be used to produce a "rational" nullspace basis obtained from the reduced row echelon form of the matrix. If

$$A = \begin{bmatrix} 1 & 1 & 1 & -1 \\ 1 & 1 & 1 & -1 \\ 1 & 1 & 1 & 1 \end{bmatrix}$$

then the command U = null(A) will produce the matrix

```
U =
   -0.8165   -0.0000
    0.4082    0.7071
    0.4082   -0.7071
   -0.0000    0.0000
```

where the entries of U are shown in MATLAB®'s format short (with four-digit mantissas). The column vectors of U form an orthonormal basis for the nullspace of A. The command R = null(A, 'r') will produce a matrix R whose columns form a simple basis for the nullspace.

```
R =
   -1   -1
    1    0
    0    1
    0    0
```

2. MATLAB® defines the numerical rank of a matrix to be the number of singular values of the matrix that are greater than

$$\mathsf{max(size(A)) * eps(norm(A))}$$

Let H be the 12×12 Hilbert matrix. The singular values of H can be computed using the command s = svd(H). The smallest singular values are $\mathsf{s}(11) \approx 2.65 \times 10^{-14}$ and $\mathsf{s}(12) \approx 1.07 \times 10^{-16}$. Since the value of $12 * \mathsf{eps}(\mathsf{normH})$ is approximately 2.66×10^{-15}, the computed value of rank(H) will be the numerical rank 11, even though the exact rank of H is 12. The computed value of cond(H) is approximately 1.8×10^{16} and the computed value of rcond(H) is approximately 2.6×10^{-17}.

88.6 Eigenvalues and Eigenvectors

MATLAB®'s eig function can be used to compute both the eigenvalues and eigenvectors of a matrix.

Commands:

1. The eig command. Given a square matrix A, the command e = eig(A) will generate a column vector e whose entries are the eigenvalues of A. The command [X, D] = eig(A) will generate a matrix X whose column vectors are the eigenvectors of A and a diagonal matrix D whose diagonal entries are the eigenvalues of A.
2. The eigshow command. MATLAB®'s eigshow utility provides a visual demonstration of eigenvalues and eigenvectors of 2×2 matrices. The utility is invoked by the command eigshow(A). The input argument A must be a 2×2 matrix. The command can also be used with no input argument, in which case MATLAB® will take [1 3; 4 2]/4 as the default 2×2 matrix. The eigshow utility shows how the image $A\mathbf{x}$ changes as we rotate a unit vector $\mathbf{x}$ around a circle. This rotation is carried out manually using a mouse. If A has real eigenvalues, then we can observe the eigenvectors of the matrix when the vectors $\mathbf{x}$ and $A\mathbf{x}$ are in the same or opposite directions.
3. The command $\mathsf{J} = \mathsf{jordan}(A)$ can be used to compute the Jordan canonical form of a matrix A. This command will only give accurate results if the entries of A are exactly represented, i.e., the entries must be integers or ratios of small integers. The command $[\mathsf{X}, \mathsf{J}] = \mathsf{jordan}(A)$ will also compute the similarity matrix X so that $A = XJX^{-1}$.
4. The following table lists some additional MATLAB® functions that are useful for eigenvalue related problems.

Function	**Command Syntax**	**Description**
poly	p = poly(A)	The characteristic polynomial of a matrix
hess	H= hess(A) or [U , H] = hess(A)	The Hessenberg form
schur	T= schur(A) or [U , T] = schur(A)	The Schur decomposition
qz	[E,F,Q,Z]=qz(A,B)	QZ factorization for generalized eigenvalues
condeig	s = condeig(A)	Condition numbers for the eigenvalues of A
expm	E = expm(A)	The matrix exponential

88.7 Sparse Matrices

A matrix is *sparse* if most of its entries are zero. MATLAB® has a special data structure for handling sparse matrices. This structure stores the nonzero entries of a sparse matrix together with their row and column indices.

Commands:

1. The command `sparse` is used to generate sparse matrices. When used with a single input argument, the command

   $$\mathsf{S} = \mathsf{sparse(A)}$$

   will convert an ordinary MATLAB® matrix A into a matrix S having the sparse data structure. More generally a command of the form

   $$\mathsf{S} = \mathsf{sparse(i, j, s, m, n, nzmax)}$$

   will generate an $m \times n$ sparse matrix S whose nonzero entries are the entries of the vector s. The row and column indices of the nonzero entries are given by the vectors i and j. The last input argument `nzmax` specifies the total amount of space allocated for nonzero entries. If the allocation argument is omitted, by default MATLAB® will set it to equal the value of `length(s)`.
2. MATLAB®'s `spy` command can be used to plot the sparsity pattern of a matrix. In these plots the matrix is represented by a rectangular box with dots corresponding to the positions of its nonzero entries.
3. The MATLAB® directory SPARFUN contains a large collection of MATLAB® functions for working with sparse matrices. The general sparse linear algebra functions are given in the following table.

MATLAB® Function	**Description**
eigs	A few eigenvalues, using ARPACK
svds	A few singular values, using eigs
luinc	Incomplete LU factorization
cholinc	Incomplete Cholesky factorization
normest	Estimate the matrix 2-norm
condest	1-norm condition number estimate
sprank	Structural rank

   All of these functions require a sparse matrix as an input argument. All have one basic output argument except in the case of `luinc` where the basic output consists of the L and U factors.
4. The SPARFUN directory also includes a collection of routines for the iterative solution of sparse linear systems.

MATLAB® Function	**Description**
pcg	Preconditioned Conjugate Gradients Method
bicg	BiConjugate Gradients Method
bicgstab	BiConjugate Gradients Stabilized Method
cgs	Conjugate Gradients Squared Method
gmres	Generalized Minimum Residual Method
lsqr	Conjugate Gradients on the Normal Equations
minres	Minimum Residual Method
qmr	Quasi-Minimal Residual Method
symmlq	Symmetric LQ Method

If A is a sparse coefficient matrix and B is a matrix of right-hand sides, then one can could solve the equation $AX = B$ using a command of the form $\mathsf{X} = \mathsf{fname(A, B)}$, where fname is one of the iterative solver functions in the table.

Examples:

1. The command

$$\mathsf{S} = \mathsf{sparse}([25, 37, 8], [211, 15, 92], [4.5, 3.2, 5.7], 200, 300)$$

will generate a 200×300 sparse matrix S whose only nonzero entries are

$$s_{25,211} = 4.5, \quad s_{37,15} = 3.2 \quad s_{8,92} = 5.7$$

2. The command $\mathsf{B} = \mathsf{bucky}$ will generate the 60×60 sparse adjacency matrix B of the connectivity graph of the Buckminster Fuller geodesic dome and the command spy(B) will generate the spy plot shown in Figure 88.1.

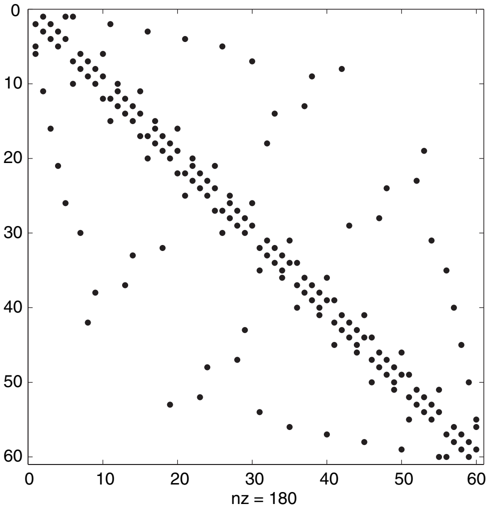

FIGURE 88.1 Spy(B).

88.8 Programming

MATLAB® has built in all of the main structures one would expect from a high level computer language. The user can extend MATLAB® by adding on programs and new functions.

Facts:

1. MATLAB® programs are called *M-files* and should be saved with a .m extension.
2. MATLAB® programs may be in the form of *script* files that list a series of commands to be executed when the file is called in a MATLAB® session, or they can be in the form of MATLAB® functions.
3. MATLAB® programs frequently include for loops, while loops, and if statements.
4. A function file must start with a function statement of the form

$$\mathsf{function} \quad [\,\mathsf{oarg1}, \ldots, \mathsf{oargk}\,] = \mathsf{fname}(\mathsf{iarg1}, \ldots, \mathsf{iargj})$$

where `fname` is the name of the function, `iarg1,...,iargj` are its input arguments, and `oarg1,...,oargk` are the output arguments. In calling a MATLAB® function it is not necessary to use all of the input and output allowed for in the general syntax of the command. In fact, MATLAB® functions are commonly used with no output arguments whatsoever.

5. One can use the same MATLAB® command with varying amounts of input and output arguments. MATLAB® keeps track of the number of input and output arguments included in the call statement using the functions `nargin` (the number of input arguments) and `nargout` (the number of output arguments). These commands are used inside the body of a MATLAB® function to tailor the computations and output to the specifications of the calling statement.
6. A MATLAB® function M-file may include subfunctions in addition to the primary function. A subfunction is another function file constructed for use by the primary file and other subfunctions of the primary file. The commands defining the subfunctions have the same form as those regular MATLAB® functions. The first subfunction file is appended to the end of the M-file for the primary function and as additional subfunctions are added, they are also appended to the end of the existing file.
7. MATLAB® has six relational operators that are used for comparisons of scalars or elementwise comparisons of arrays. These operators are:

Relational Operators	
$<$	less than
$<=$	less than or equal
$>$	greater than
$>=$	greater than or equal
$==$	equal
$\sim=$	not equal

8. There are four logical operators as shown in the following table:

Logical Operators	
&	AND
|	OR
`xor`	Exclusive OR
$\sim$	NOT

These logical operators regard any nonzero scalar as corresponding to TRUE and 0 as corresponding to FALSE. The operator & corresponds to the logical AND. If a and b are scalars, the expression $a\&b$ will equal 1 if a and b are both nonzero (TRUE) and 0 otherwise. The operator | corresponds to the logical OR. The expression $a|b$ will have the value 0 if a and b are both 0 and otherwise it will be equal to 1. The exclusive or operator `xor(a,b)` is logical 1 (TRUE) when either a or b, but not both, is non-zero. The operator $\sim$ corresponds to the logical NOT. For a scalar a, the expression $\sim a$ takes on the value 1 (TRUE) if $a = 0$ (FALSE) and the value 0 (FALSE) if $a \neq 0$ (TRUE). There are also short circuit versions && and || of the *and* and *or* operators. In the case that $a = 0$ (FALSE), the short circuit *and* operator `a && b` will take on the value 0 (FALSE) without even considering the value of b and in the case that $a \neq 0$, the short circuit *or* operator `a || b` will take on the value 1 (TRUE) without even considering the value of b

For matrices these operators are applied elementwise. Thus, if A and B are both $m \times n$ matrices, then $A\&B$ is a matrix of zeros and ones whose (i, j) entry is $a(i, j)\&b(i, j)$.

Examples:

1. Given two $m \times n$ matrices A and B, the command $\mathsf{C} = \mathsf{A} < \mathsf{B}$ will generate an $m \times n$ matrix consisting of zeros and ones. The (i, j) entry will be equal to 1 if and only if $a_{ij} < b_{ij}$. If

$$A = \begin{bmatrix} -1 & 1 & 0 \\ 4 & -2 & 5 \\ 1 & -3 & -2 \end{bmatrix}$$

then command $A >= 0$ will generate

```
ans =

        0  1  1

        1  0  1

        1  0  0
```

2. If

$$A = \begin{bmatrix} 3 & 0 \\ 0 & 2 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 0 & 2 \\ 0 & 3 \end{bmatrix}$$

then

$$A \&\& B = A \& B = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}, \quad A || B = A | B = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$$

$$\sim\! A = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad \mathsf{xor}(A, B) = \begin{bmatrix} 1 & 1 \\ 0 & 0 \end{bmatrix}$$

3. If the numerical nullity of a matrix is defined to be the number of columns of the matrix minus the numerical rank of the matrix, then one can create a file *numnull.m* to compute the numerical nullity of a matrix. This can be done using the following lines of code.

```
function  k = numnull(A)
% The command numnull(A) computes the numerical nullity of A
[m,n] = size(A);
k = n − rank(A);
```

The line beginning with the % is a comment that is not executed. It will be displayed when the command `help numnull` is executed. The semicolons suppress the printouts of the individual computations that are performed in the function program.

4. The following is an example of a MATLAB® function to compute the circle that gives the best least squares fit to a collection of points in the plane.

```
function [center,radius,e] = circfit(x,y,w)
% The command [center,radius] = circfit(x,y) generates
% the center and radius of the circle that gives the
% best least squares fit to the data points specified
% by the input vectors x and y. If a third input
% argument is specified then the circle and data
% points will be plotted. Specify a third output
% argument to get an error vector showing how much
% each point deviates from the circle.
if size(x,1) == 1, x = x'; end
if size(y,1) == 1, y = y'; end
A = [2∗ x, 2∗ y, ones(size(x))];
b = x.^2 + y.^2;
c = A\b;
center = c(1:2)';
```

```
radius = sqrt(c(3) + c(1)^2 + c(2)^2);
if nargin > 2
        t = 0:0.1:6.3;
        u = c(1) + radius*cos(t);
        v = c(2) + radius*sin(t);
        plot(x,y,'x',u,v)
        axis equal
end
if nargout == 3
        e = sqrt((x − c(1)).^2 + (y − c(2)).^2) − radius;
end
```

The command `plot(x,y,'x',u,v)` is used to plot the original (x, y) data as discrete points in the plane, with each point designated by an "x", and to also, on the same axis system, plot the (u, v) data points as a continuous curve. MATLAB® plot commands are explained in greater detail in Section 88.10

88.9 Function Handles and Anonymous Functions

MATLAB® has a structure called a *function handle* that allows one to construct simple anonymous functions interactively in a MATLAB® session.

Facts:

1. A function handle for a function of the variables $x1, x2, \ldots xk$ is generated by a statement of the form

   $$\mathsf{functionname} = @(\mathsf{x1}, \mathsf{x2}, \ldots, \mathsf{xk})\ \mathsf{function\ rule}$$

   where `function rule` is an algebraic expression defining the function.
2. Some MATLAB® functions require input arguments involving user defined or built-in MATLAB® functions. In such cases a function handle provides a convenient way to include a function as an input argument. The MATLAB® directory `funfun` consists of a collection of MATLAB® M-file functions that require functions as input arguments.

Examples:

1. To construct the function $g(t) = 3\cos t - 2\sin t$ interactively set

   $$\mathsf{g} = @(\mathsf{t})\ 3 * \mathsf{cos}(\mathsf{t}) - 2 * \mathsf{sin}(\mathsf{t})$$

   If one then enters `g(0)` on the command line, MATLAB® will return the answer 3. The function g can be used as an input argument for MATLAB® functions. For example, the command `ezplot(g)` will produce a plot of the graph of $g(t)$. (See Section 88.10 for more information on producing graphics.)
2. The MATLAB® function `quad` is used to compute definite integrals. The user must specify both the function and the end points of the interval as input arguments. For example, $\int_0^1 \frac{4}{1+x^2}\,dx$ can be calculated using the commands

   $$\mathsf{f} = @(\mathsf{x})\ 4./(1 + \mathsf{x}.\hat{}2); \quad \mathsf{quad}(\mathsf{f}, 0,\ 1)$$

   or by using the single command

   $$\mathsf{quad}(@(\mathsf{x})\ 4./(1 + \mathsf{x}.\hat{}2), 0,\ 1)$$

In either case, MATLAB® will return the value 3.1416 which is correct to the number of digits displayed.

3. To construct the function $f(x, y) = 2x \sin y + 3y \cos x$ interactively set

$$\mathsf{f} = @(\mathsf{x},\mathsf{y})\ 2 * \mathsf{x}. * \mathsf{sin}(\mathsf{y}) + 3 * \mathsf{y}. * \mathsf{cos}(\mathsf{x})$$

The command `f(0,1)` will return the answer 3. The command `ezsurf (f)` will produce a surface plot of the function. (See Sections 88.10 and 88.11 for more information on producing graphics.)

88.10 Graphics

MATLAB® graphics utilities allow the user to do simple two- and three-dimensional plots as well as more sophisticated graphical displays.

Facts:

1. MATLAB® incorporates an objected oriented graphics system called *Handle Graphics.* This system allows the user to modify and add on to existing figures and is useful in producing computer animations.
2. MATLAB®'s graphics capabilities include digital imaging tools. MATLAB® images may be indexed or true color.
3. An indexed image requires two matrices, a $k \times 3$ colormap matrix whose rows are triples of numbers that specify red, green, blue intensities, and an $m \times n$ image matrix whose entries assign a colormap triple to each pixel of the image.
4. A true color image is one derived from an $m \times n \times 3$ array, which specifies the red, green, blue triplets for each pixel of the image.

Commands:

1. The `plot` command is used for simple plots of x-y data sets. Given a set of (x_i, y_i) data points, the command `plot(x,y)` plots the data points and by default sequentially draws line segments to connect the points. A third input argument may be used to specify a color (the default color for plots is black) or to specify a different form of plot such as discrete points or dashed line segments.
2. The `ezplot` command is used for plots of functions. The command `ezplot(f)` plots the function $f(x)$ on the default interval $(-2\pi, 2\pi)$ and the command `ezplot(f,[a,b])` plots the function over the interval [a,b].
3. The commands `plot3` and `ezplot3` are used for three-dimensional plots.
4. The command `meshgrid` is used to generate an xy-grid for surface and contour plots. Specifically, the command `[X, Y] = meshgrid(u, v)` transforms the domain specified by vectors `u` and `v` into arrays `X` and `Y` that can be used for the evaluation of functions of two variables and three-dimensional surface plots. The rows of the output array `X` are copies of the vector `u` and the columns of the output array `Y` are copies of the vector `v`. The command can be used with only one input argument in which case `meshgrid(u)` will produce the same arrays as the command `meshgrid(u,u)`.
5. The `mesh` command is used to produce wire frame surface plots and the command `surf` produces a solid surface plot. If `[X, Y] = meshgrid(u, v)` and $Z(i, j) = f(u_i, v_j)$, then the command `mesh(X,Y,Z)` will produce a wire frame plot of the function $z = f(x, y)$ over the domain specified by the vectors `u` and `v`. Similarly, the command `surf(X,Y,Z)` will generate a surface plot over the domain.

6. The MATLAB® functions `contour` and `ezcontour` produce contour plots for functions of two variables.
7. The command `meshc` is used to graph both the mesh surface and the contour plot in the same graphics window. Similarly the command `surfc` will produce a `surf` plot with a contour graph appended.
8. Given an array C whose entries are all real, the command `image(C)` will produce a two-dimensional image representation of the array. Each entry of C will correspond to a small patch of the image. The image array C may be either $m \times n$ or $m \times n \times 3$. If C is an $m \times n$ matrix, then the colors assigned to each patch are determined by MATLAB®'s current colormap. If C is $m \times n \times 3$, a true color array, then no color map is used. In this case, the entries of C(:, :, 1) determine the red intensities of the image, the entries of C(:, :, 2) determine green intensities, and the elements of C(:, :, 3) define the blue intensities.
9. The `colormap` command is used to specify the current colormap for image plots of $m \times n$ arrays.
10. The `imread` command is used to translate a standard graphics file such as a gif, jpeg, or tiff file, into a true color array. The command can also be used with two output arguments to determine an indexed image representation of the graphics file.

Examples:

1. The graph of the function $f(x) = \cos(x) + \sin^2(x)$ on the interval $(-2\pi, 2\pi)$ can be generated in MATLAB® using the following commands:

```
x = −6.3: 0.1:6.3;
y = cos(x) + sin(x).^2;
plot(x,y)
```

The graph can also be generated using the ezplot command. (See Figure 88.2.)

```
f = @(x)cos(x) + sin(x)^2
ezplot(f)
```

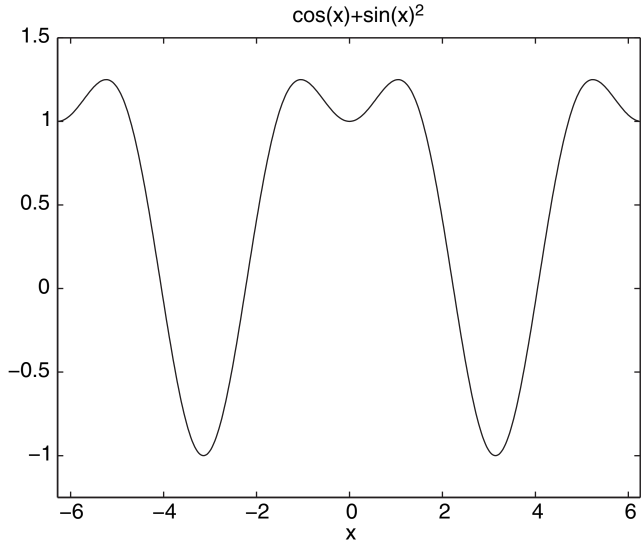

FIGURE 88.2 The graph for Example 1.

2. We can generate a three-dimensional plot using the following commands:

```
t = 0 : pi/50 : 10*pi;
plot3(t.^2.*sin(5*t), t.^2.*cos(5*t), t)
grid on
axis square
```

These commands generate the plot shown in Figure 88.3.

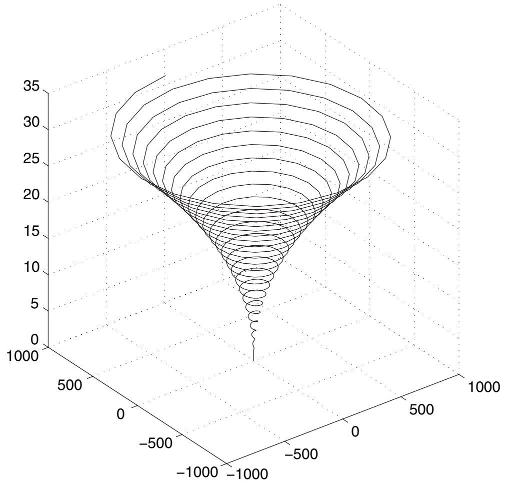

FIGURE 88.3 The graph for Example 2.

3. MATLAB®'s peaks function is a function of two variables obtained by translating and scaling Gaussian distributions. The commands

```
[X,Y] = meshgrid(-3:0.1:3);
Z = peaks(X,Y);
meshc(X,Y,Z);
```

generate the mesh and contour plots of the peaks function. (See Figure 88.4)

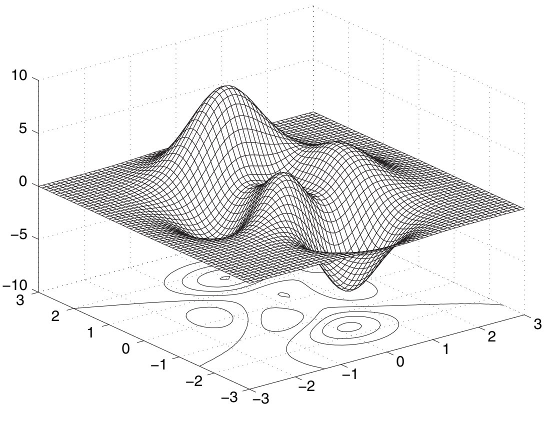

FIGURE 88.4 The graph for Example 3.

88.11 Symbolic Mathematics in MATLAB®

MATLAB®'s Symbolic Toolbox is based upon the symbolic software package MuPAD. All symbolic computations in MATLAB® are performed by the MuPAD software. The toolbox allows users to do various types of symbolic computations using either the MATLAB® interface with standard MATLAB® commands or the MuPAD notebook interface.

Facts:

1. The MuPAD symbolic software was originally developed by a research group at the University of Paderborn, Germany. The software was distributed by SciFace until the company was bought out by Mathworks in September 2008. At that point, MuPAD replaced Maple as the kernel for MATLAB®'s symbolic toolbox.
2. For the standard MATLAB® interface, the symbolic toolbox uses a new data type, symbolic objects. The user can create symbolic variables and symbolic matrices (arrays containing symbolic variables).
3. The standard matrix operations $+$, $-$, $*$, $\hat{}$, $'$ all work for symbolic matrices and also for combinations of symbolic and numeric matrices. To add a symbolic matrix and a numeric matrix, MATLAB® first transforms the numeric matrix into a symbolic object and then performs the addition using MuPAD. The result will be a symbolic matrix. In general if the matrix operation involves at least one symbolic matrix, then the result will be a symbolic matrix.
4. Standard MATLAB® commands such as `det`, `inv`, `eig`, `null`, `trace`, `rref`, `rank`, and `sum` all work for symbolic matrices.
5. Not all of the MATLAB® matrix commands work for symbolic matrices. Commands such as `norm` and `orth` do not work and none of the standard matrix factorizations such as LU or QR work.
6. MATLAB®'s symbolic toolbox supports variable precision floating arithmetic.
7. Symbolic computations can also be carried out using the MuPAD notebook interface. A MuPAD notebook is a convenient environment for performing computations symbolically using the MuPAD language and documenting the results.
8. The MuPAD notebook interface incorporates graphics and typeset math for documenting and managing computations performed with the MuPAD language.
9. The main work area in a MuPAD notebook consists of input regions where commands are entered, output regions where the results of the computations (including graphics) are displayed, and text regions where the user can enter text to describe and annotate the calculations. To the right of the main work area is a command bar that can be used for quick access to standard mathematical functions.
10. MuPAD includes libraries covering common mathematical areas, such as calculus and linear algebra, and specialized areas, such as number theory and combinatorics
11. MuPAD has functions for converting symbolic expressions to MATLAB®, Fortran, MathML, C, and TeX.
12. The MuPAD editor and debugger can be used to create custom symbolic functions and libraries.
13. The MuPAD programming language supports object oriented programming.

Commands:

1. The `sym` command can be used to transform any MATLAB® data structure into a symbolic object. If the input argument is a string, the result is a symbolic number or

variable. If the input argument is a numeric scalar or matrix, the result is a symbolic representation of the given numeric values.

2. The `syms` command allows the user to create multiple symbolic variables with a single command.
3. The command `subs` is used to substitute for variables in a symbolic expression.
4. The command `colspace` is used to find a basis for the column space of a symbolic matrix.
5. The commands `ezplot`, `ezplot3`, and `ezsurf` are used to plot symbolic functions of one or two variables.
6. The command `vpa(A,d)` evaluates the matrix `A` using variable precision floating point arithmetic with d decimal digits of accuracy. The default value of `d` is 32, so if the second input argument is omitted, the matrix will be evaluated with 32 digits of accuracy.
7. The command `NB = MuPAD` opens a new blank MuPAD notebook and returns an object representing the notebook. The command `NB = MuPAD(FileName)` opens the notebook with file name `FileName`.
8. The command `MuPADdemo` will bring up a menu of demo MuPAD notebooks along with a short description of each demo.

Examples:

1. The command

```
t = sym('t')
```

   transforms the string 't' into a symbolic variable `t`. Once the symbolic variable has been defined, one can then perform symbolic operations. For example, the command

```
factor(t^2 − 4)
```

   will result in the answer

```
(t − 2) ∗ (t + 2)
```

2. The command

```
syms  a  b  c
```

   creates the symbolic variables `a`, `b`, and `c`. If we then set

```
A = [a,  b,  c;  b,  c,  a;  c,  a,  b]
```

   the result will be the symbolic matrix

```
A=
   [a, b, c]
   [c, a, b]
   [b, c, a]
```

   Note that for a symbolic matrix the MATLAB® output is in the form of a matrix of row vectors with each row vector enclosed by square brackets.

3. Let A be the matrix defined in the previous example. We can add the 3 × 3 Hilbert matrix to A using the command `B = A + hilb(3)`. The result is the symbolic matrix

```
B=
     [a + 1, b + 1/2, c + 1/3]
   [c + 1/4, a + 1/5, b + 1/6]
   [b + 1/7, c + 1/8, a + 1/9]
```

To substitute 2 for `a` in the matrix `A` we set

```
A = subs(A, a, 2)
```

The matrix `A` then becomes

```
A=
   [2, b, c]
   [c, 2, b]
   [b, c, 2]
```

Multiple substitutions are also possible. To replace `b` by `b + 1` and `c` by 5, one need only set

```
A = subs(A, [b, c], [b + 1, 5])
```

4. If a is declared to be a symbolic variable, the command

   ```
   A = [1 2 1; 2 4 2; 0 0 a]
   ```

   will produce the symbolic matrix

   ```
   A=
      [1, 2, 1]
      [2, 4, 6]
      [0, 0, a]
   ```

   The eigenvalues 0, 5, and a are computed using the command `eig(A)`. The command

   ```
   [X, D] = eig(A)
   ```

   generates a symbolic matrix of eigenvectors

   ```
   X=
      [−2,      1/2 ∗ (a + 8)/(−2 + 3 ∗ a), 1]
      [  1,                               1, 2]
      [  0,  1/2 ∗ a ∗ (a − 5)/(−2 + 3 ∗ a), 0]
   ```

   and the diagonal matrix

   ```
   D=
      [0, 0, 0]
      [0, a, 0]
      [0, 0, 5]
   ```

   When $a = 0$ the matrix A will be defective. One can substitute 0 for a in the matrix of eigenvectors using the command

   ```
   X = subs(X, a, 0)
   ```

   This produces the numeric matrix

   ```
   X=
     −2  −2  1
      1   1  2
      0   0  0
   ```

5. If we set `z = exp(1)`, then MATLAB® will compute an approximation to e that is accurate to 16 decimal digits. The command `vpa(z)` will produce a 32 digit representation of z, but only the first 16 digits will be accurate approximations to the digits of e. To compute e more accurately one should apply the `vpa` function to the symbolic expression `'exp(1)'`. The command `z = vpa('exp(1)')` produces an answer `z = 2.7182818284590452353602874713527`, which is accurate to 32 digits.

88.12 Graphical User Interfaces

A graphical user interface (GUI) is a user interface whose components are graphical objects such as pushbuttons, radio buttons, text fields, sliders, checkboxes, and menus. These interfaces allow users to perform sophisticated computations and plots simply by typing numbers into boxes, clicking on buttons, or moving slidebars.

Commands:

1. The command `guide` opens up the MATLAB® GUI Design Environment. This environment is essentially a GUI containing tools to facilitate the creation of new GUIs.

Examples:

1. Thomas G. Wright of Oxford University has developed a MATLAB® GUI, `eigtool`, for computing eigenvalues, pseudospectra, and related quantities for nonsymmetric matrices, both dense and sparse. It allows the user to graphically visualize the pseudospectra and field of values of a matrix with just the click of a button.
   The *epsilon-pseudospectrum* of a square matrix A is defined by

$$\Lambda_\epsilon(A) = \{z \in C \mid z \in \sigma(A+E) \text{ for some } E \text{ with } \|E\| \leq \epsilon\} \qquad (88.2)$$

   In Figure 88.6 the `eigtool` GUI is used to plot the epsilon-pseudospectra of a 10×10 matrix for $\epsilon = 10^{-k/4}$, $k = 0, 1, 2, 3, 4$.
   For further information, see Chapter 23 and also references [Tre99] and [WT01].
2. The NSF sponsored ATLAST Project has developed a large collection of MATLAB® exercises, projects, and M-files for use in elementary linear algebra classes. (See [LHF03].) The

ATLAST M-file collection contains a number of programs that make use of MATLAB®'s GUI features to present user friendly tools for visualizing linear algebra. One example is the ATLAST `cogame` utility where students play a game to find linear combinations of two given vectors with the objective of obtaining a third vector that terminates at a given target point in the plane. Students can play the game at any one of four levels or play it competitively by selecting the two-person game option. (See Figure 88.7.) At each step of the game a player must enter a pair of coordinates. MATLAB® then plots the corresponding linear combination as a directed line segment. The game terminates when the tip of the plotted line segment lies in the small target circle. A running list of the coordinates entered in the game is displayed in the lower box to the left of the figure. The `cogame` GUI is useful for teaching lessons on the span of vectors in R^2 and for teaching about different bases for R^2.

3. The ATLAST `transform` GUI helps students to visualize the effect of linear transformations on figures in the plane. With this utility students choose an image from a list of figures and then apply various transformations to the image. Each time a transformation is applied, the resulting image is shown in the current image window. The user can then click on the *current transformation* button to see the matrix representation of the transformation that maps the original image into the current image. In Figure 88.8, two transformations were applied to an initial image. First a 45° rotation was applied. Next a transformation matrix $[1, 0;\ 0.5, 1]$ was entered into the "Your Transformation" text field and the corresponding transformation was applied to the lower left image with the result being displayed in the Current Image window on the lower right. To transform the Current Image into the Target Image directly above it, one would need to apply a reflection transformation.

89.1 Introduction

Maple® is a general purpose computational system offering symbolic computation, exact and approximate (floating-point) numerical computation, and scientific plotting and graphics. The main Maple library is written in the Maple programming language, a rich language that allows easy access to advanced mathematical algorithms. A special feature of Maple is access for users to much of the library source code, including the ability to trace Maple's own execution; the only parts of Maple that cannot be traced are those parts that are compiled, for example, the kernel. Users can also link to LAPACK and NAG library routines transparently, and thus benefit from fast and reliable floating-point computation. Maple was started in the early 1980s, and the Maplesoft company was founded in 1988.

There are two linear algebra packages in Maple: `LinearAlgebra` and `linalg`. The `linalg` package is older and is considered obsolete; it was replaced by `LinearAlgebra` in MAPLE 6. We describe here only the `LinearAlgebra` package, as contained in MAPLE 17. The reader should be careful when reading other reference books, or the Maple help pages, to check whether the functions being discussed include the obsolete functions `vector, matrix, array` (notice the lower-case initial letter) of the older package, or include `Vector, Matrix, Array` (with an upper-case initial letter), which are part of the newer package.

Maple's `LinearAlgebra` package uses a strict data typing based on the notions of abstract linear algebra [Jac53]. There are strict distinctions between scalars, vectors, matrices, and arrays, of which users should be aware. Another feature of Maple's linear algebra arises because of the additional considerations that are required in the context of symbolic computation. These considerations are usually omitted from standard texts, and are the subject of additional comments here.

Facts:

1. Maple offers a number of interface options, including the two GUI interfaces "Worksheet mode" and "Document mode", and also a non-GUI command-line interface. We concentrate here on the MAPLE 17 worksheet mode.
2. Maple commands are typed after a prompt symbol, which by default is [>, or just >. In examples below, keyboard input is simulated by prefixing the actual command typed with the prompt symbol >.
3. In Maple examples below, white space is used to enhance readability. Maple ignores extra spaces. Also, comments within the code are preceded by # .
4. In some of the examples below, a command is too long to fit on one line. In worksheet mode, shift-enter continues to a new line, and no continuation character is printed; in command-line Maple, the continuation character backslash (\ ) is used. Here we use the worksheet convention. When typing long examples into Maple, either shift-enter can be typed when the end of the line as printed here is reached, or one can ignore the new line and continue typing, allowing Maple to wrap the command.
5. Maple commands are terminated by either semicolon (;) or colon (:). The semicolon allows the output of a command to be displayed; the colon suppresses the output display, but the command still executes. Before MAPLE 10, one of the two command terminators was required, but starting in the MAPLE 10 GUI a carriage return is equivalent to semicolon, when the default 2-D input is used.
6. To access the commands described below, load the `LinearAlgebra` package by typing the command (after the prompt, as shown)
   ```
   > with( LinearAlgebra );
   ```
   If the package is not loaded, then either a typed command will not be recognized, or a different command with the same name will be used.
7. The results of a command can be assigned to one or more variables. Thus,
   ```
   > a := 1 ;
   ```
   assigns the value 1 to the variable a, while
   ```
   > (a,b,c) := 1,2,3 ;
   ```
   assigns a the value 1, b the value 2 and c the value 3.
   Caution: The operator "colon-equals" (:=) is assignment, while the operator "equals" (=) defines an equation with a left-hand side and a right-hand side.
8. A sequence of expressions separated by commas is an expression sequence in Maple, and some commands return expression sequences, which can be assigned as above.
9. Ranges in Maple are generally defined using a pair of periods (..). The rules for the ranges of subscripts are given below.
10. Output format in Maple uses spaces to separate elements in vectors and matrices, but here for space saving we also use commas.

89.2 Vectors

Facts:

1. In Maple, vectors are not just lists of elements. Maple separates the idea of the mathematical object `Vector` from the data object `Array` (see Section 89.4).
2. A Maple `Vector` can be converted to an `Array`, and an `Array` of appropriate shape can be converted to a `Vector`, but they cannot be used interchangeably in commands. See the help file for `convert` to find out about other conversions.
3. Maple distinguishes between column vectors, the default, and row vectors. The two types of vectors behave differently, and are not merely presentational alternatives.

Commands:

1. Generation of vectors:
   - `Vector(` $[x_1, x_2, \ldots]$ `)` Construct a column vector by listing its elements. The length of the list specifies the dimension.
   - `Vector[column](` $[x_1, x_2, \ldots$ `]` `)` Explicitly declare the column attribute.
   - `Vector[row](` $[x_1, x_2, \ldots$ `]` `)` Construct a row vector by initializing its elements from a list.
   - $<v_1, v_2, \ldots>$ Construct a column vector with elements v_1, v_2, etc. An element can be another column vector.
   - $<v_1|v_2|\ldots$ `>` Construct a row vector with elements v_1, v_2, etc. An element can be another row vector. A useful mnemonic is to think of the bars, | , as column dividers in a table.
   - `Vector( n, k−>f(k) )`. Construct an n-dimensional vector using a function $f(k)$ to define the elements. $f(k)$ is evaluated sequentially for k from 1 to n. The notation `k−>f(k)` is Maple syntax for a univariate function.
   - `Vector( n, fill=v )` An n-dimensional vector with every element equal to v.
   - `Vector( n, symbol=v )` An n-dimensional vector containing symbolic components v_k.
   - `map( x−>f(x), V )` Construct a new vector by applying function $f(x)$ to each element of the vector named `V`. Caution: the command is `map` not `Map`. Several Maple packages, including `LinearAlgebra`, define a command `Map`, but the command `map` is easier to use.
   - `RandomVector( n, generator= a .. b)` Construct a vector with random integer entries taken from the interval $[a, b]$. The default is $[-99, 99]$.
2. Operations and functions:
   - `v[i]` Element i of vector **v**. The result is a scalar. Caution: A symbolic reference `v[i]` is typeset as v_i on output in a Maple worksheet.
   - `v[p..q]` Vector consisting of elements v_i, $p \le i \le q$. The result is a `Vector`, even for the case `v[p..p]`. Either of p or q can be negative, meaning that the location is found by counting backward from the end of the vector, with -1 being the last element.
   - `u+v, u-v` Add or subtract `Vectors` **u**, **v**.
   - `a*v` Multiply vector **v** by scalar a. Notice the operator is "asterisk" ($*$).
   - `u . v`, `DotProduct( u, v )` The inner product of `Vectors` **u** and **v**. See examples for complex conjugation rules. Notice the operator is "period" (.) not "asterisk" ($*$) because inner product is not commutative over the field of complex numbers.
   - `Transpose( v ), v∧%T` Change a column vector into a row vector, or vice versa. Complex elements are not conjugated.
   - `HermitianTranspose( v ), v∧%H` Transpose with complex conjugation.
   - `OuterProductMatrix( u, v )` The outer product of `Vectors` **u** and **v** (ignoring the attributes of row or column).
   - `CrossProduct( u, v ), u &x v` The vector product, or cross product, of three-dimensional vectors **u**, **v**.
   - `Norm( v )` The infinity norm of a vector **v**. The infinity norm is chosen rather than the 2-norm because in a symbolic context the infinity norm is usually easier to compute and it leads to less unwieldy expressions than the 2-norm.
   - `Norm( v, 2 )` The 2-norm or Euclidean norm of vector **v**. Notice that the second argument, namely the 2, is necessary because `Norm( v )` is the infinity norm, which is different from the default in many textbooks and software packages.
   - `Norm( v, p )` The p-norm of **v**, namely $\left(\sum_{i=1}^{n} |v_i|^p\right)^{(1/p)}$.

Examples:

In Example 5 below, the imaginary unit is the Maple default I. That is, $\sqrt{-1} = I$. In the matrix section, we show how this can be changed. To save space, we shall mostly use row vectors.

1. Generate vectors. The same vector created different ways.

```
> Vector[row]([0,3,8]): <0|3|8>: Transpose(<0,3,8>): Vector[row]
(3,i->i∧2-1);
```

$$[0, 3, 8]$$

2. Selecting elements.

```
> V:=<a|b|c|d|e|f>: V1 := V[2 .. 4]; V2:=V[-4 .. -1];
V3:=V[-4 .. 4];
```

$$V1 := [b, c, d]\ , \quad V2 := [c, d, e, f]\ , \quad V3 := [c, d]$$

3. A Gram–Schmidt exercise.

```
> u1 := <3|0|4>: u2 := <2|1|1>: w1n := u1/Norm( u1, 2 );
```

$$w1n := [3/5, 0, 4/5]$$

```
> w2 := u2 - (u2 . w1n)*w1n; w2n := w2/Norm( w2, 2 );
```

$$w2n := \left[\frac{2\sqrt{2}}{5}, \frac{\sqrt{2}}{2}, -\frac{3\sqrt{2}}{10}\right]$$

4. Comparison of norms in a symbolic setting:

```
> V:= Vector( 1,3,x,y): [ Norm(V), Norm(V,2) ] ;
```

$$\left[\ \max(3, |x|, |y|), \sqrt{10 + |x|^2 + |y|^2}\ \right]$$

5. Vectors with complex elements. Define column vectors $\mathbf{u_c}$,$\mathbf{v_c}$ and row vectors $\mathbf{u_r}$,$\mathbf{v_r}$.

```
> uc := <1 + I,2>: ur := Transpose( uc ): vc := <5,2 − 3*I>:
vr := Transpose( vc ):
```

The inner product of column vectors conjugates the first vector in the product, and the inner product of row vectors conjugates the second.

```
> inner1 := uc . vc; inner2 := ur . vr;
                inner1 := 9-11 I   , inner2 := 9+11 I
```

Maple computes the product of two similar vectors, i.e., both rows or both columns, as a true mathematical inner product, since that is the only definition possible; in contrast, if the user mixes row and column vectors, then Maple does not conjugate:

```
> but := ur . vc;
```

$$but := 9 - I$$

Caution: The use of a period (.) with complex row and column vectors together differs from the use of a period (.) with complex $1 \times m$ and $m \times 1$ matrices. In case of doubt, use matrices and conjugate explicitly where desired.

89.3 Matrices

Facts:

1. One-column matrices and vectors are not interchangeable in Maple.
2. Matrices and two-dimensional arrays are not interchangeable in Maple.

Commands:

1. Generation of Matrices. This can be done using either the `Matrix` command or using angle bracket notation << ... >>. Owing to recent improvements in Maple, they are of comparable efficiency.

   - `Matrix( [[a,b,...],[c,d,...],...] )` Construct a matrix row-by-row, using a list of lists.
   - $< a, b, \ldots; c, d, \ldots; \ldots >$ Construct a matrix using MATLAB-style syntax.
   - `<< a|b|...>,<c|d|...>,...>` Construct a matrix row-by-row using vectors. Notice that the rows are specified by row vectors, requiring the | notation.
   - `<< a,b,...>|< c,d,...>|...>` Construct a matrix column-by-column using vectors. Notice that each vector is a column, and the columns are joined using | .
   - `Matrix( n, m, (i,j)->f(i,j) )` Construct a matrix $n \times m$ using a function $f(i,j)$ to define the elements. $f(i,j)$ is evaluated sequentially for i from 1 to n and j from 1 to m. The notation `(i,j)->f(i,j)` is Maple syntax for a bivariate function $f(i,j)$.
   - `Matrix( n, m, fill=a )` An $n \times m$ matrix with each element equal to a.
   - `Matrix( n, m, symbol=a )` An $n \times m$ matrix containing subscripted entries a_{ij}.
   - `map( x->f(x), M )` A matrix obtained by applying $f(x)$ to each element of M.
     Caution: the command is `map` not `Map`. See comment in Section 89.2.
   - `<< A | B>, < C | D>>` Construct a partitioned (block) matrix from matrices A, B, C, D. Note that `< A|B >` will be formed by adjoining columns; the block `< C|D >` will be placed below `< A|B >`. The Maple syntax is similar to a common textbook notation for partitioned matrices.
   - `RandomMatrix( n, m, generator=a .. b)` Generate a matrix with random integer entries taken from the interval $[a, b]$. The default is $[-99, 99]$.

2. Operations and functions
   - `M[i,j]` Element i, j of matrix M. The result is a scalar.
   - `M[1..-1,k]` Column k of `Matrix` M. The result is a `Vector`.
   - `M[k,1..-1]` Row k of `Matrix` M. The result is a row `Vector`.
   - `M[p..q,r..s]` Matrix consisting of submatrix m_{ij}, $p \leq i \leq q$, $r \leq j \leq s$. In Handbook notation, $M[\{p, \ldots, q\}, \{r, \ldots, s\}]$.
   - `M[RowList,ColList]` Matrix with rows and columns specified by the lists (order respected).
   - `Transpose( M ), M^%T` Transpose matrix M, without taking the complex conjugate of the elements.
   - `HermitianTranspose( M ), M^%H` Transpose matrix M, taking the complex conjugate of elements.
   - `A ± B` Add/subtract compatible matrices or vectors A, B.
   - `A.B` Product of compatible matrices or vectors A, B. The examples give details of how Maple interprets products, since there are differences from other software packages.
   - `MatrixInverse( A ), A^(-1)` Inverse of matrix A.
   - `Determinant( A )` Determinant of matrix A.
   - `Norm( A )` The infinity norm of the matrix A. In a symbolic context, this norm is more practical than the 2-norm (see example).
   - `Norm( A, 2 )` The (subordinate) 2-norm of matrix A, namely $\max_{\|u\|_2 = 1} \|Au\|_2$ where the norm in the definition is the vector 2-norm.

     Cautions:
     (a) Notice that the second argument, i.e., 2, is necessary because `Norm( A )` is the infinity norm, which is different from the default in many textbooks and software packages.
     (b) Notice also that this is the largest singular value of A, and is usually different from the Frobenius norm $\|A\|_F$, accessed by `Norm( A, Frobenius )`, which is the Euclidean norm of the vector of elements of the matrix A.

(c) Unless A has floating-point entries, this norm usually will not be computable explicitly, and it may be expensive even to try.

- `Norm( A, p )` The (subordinate) matrix p-norm of A, for integers $p >= 1$ or for p being the symbol `infinity`, which is the default value.

Examples:

1. A matrix product.

```
> A := <<1|-2|3>,<0|1|1>>; B := Matrix(3, 2, symbol=b); C := A . B;
```

$$A := \begin{bmatrix} 1 & -2 & 3 \\ 0 & 1 & 1 \end{bmatrix}, \qquad B := \begin{bmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \\ b_{31} & b_{32} \end{bmatrix},$$

$$C := \begin{bmatrix} b_{11} - 2b_{21} + 3b_{31} & b_{12} - 2b_{22} + 3b_{32} \\ b_{21} + b_{31} & b_{22} + b_{32} \end{bmatrix}.$$

2. A Gram–Schmidt calculation revisited.

If u_1, u_2 are $m \times 1$ column matrices, then the Gram–Schmidt process is often written in textbooks as

$$w_2 = u_2 - \frac{u_2^T u_1}{u_1^T u_1} u_1.$$

Notice, however, that $u_2^T u_1$ and $u_1^T u_1$ are strictly 1×1 matrices. Textbooks often slide effortlessly over the conversion of $u_2^T u_1$ from a 1×1 matrix to a scalar. Maple, in contrast, does not suppose that conversion should be automatic.

Transcribing the printed formula into Maple will cause an error. Here is the way to do it. We reuse the earlier numerical data.

```
> u1 := <<3,0,4>>; u2 := <<2,1,1>>; r := u2^%T . u1;
 s := u1^%T . u1;
```

$$u1 := \begin{bmatrix} 3 \\ 0 \\ 4 \end{bmatrix}, \quad u2 := \begin{bmatrix} 2 \\ 1 \\ 1 \end{bmatrix}, \quad r := [10], \quad s := [25].$$

Notice the brackets in the values of `r` and `s`; they show us that `r` and `s` are matrices. Since `r[1,1]` and `s[1,1]` are scalars, we can write

```
> w2 := u2 - r[1,1]/s[1,1]*u1;
```

and reobtain the result from Example 89.2.3. Alternatively, $u1$ and $u2$ can be converted to `Vectors` first and then used to form a proper scalar inner product.

```
> r := u2[1..-1,1] . u1[1..-1,1]; s := u1[1..-1,1] . u1[1..-1,1]; w2 := u2-r/s*u1;
```

$$r := 10, \quad s := 25, \quad w2 := \begin{bmatrix} 4/5 \\ 1 \\ -3/5 \end{bmatrix}.$$

3. Vector–Matrix and Matrix–Vector products.

Many textbooks treat a column vector and a one-column matrix as equivalent, but this is not so in Maple. Thus,

```
> b := <1,2>; B := <<1,2>>; C := <<4|5|6>>;
```

$$b := \begin{bmatrix} 1 \\ 2 \end{bmatrix} B := \begin{bmatrix} 1 \\ 2 \end{bmatrix} C := \begin{bmatrix} 4 & 5 & 6 \end{bmatrix}.$$

Only the product `B . C` is defined, and the product `b . C` causes an error.

```
> B . C
```

$$\begin{bmatrix} 4 & 5 & 6 \\ 8 & 10 & 12 \end{bmatrix}.$$

The rules for mixed products are

```
Vector[row]( n ) . Matrix( n, m )          =  Vector[row]( m )
Matrix( n, m ) . Vector[column]( m )       =  Vector[column]( n )
```

The combinations `Vector(n). Matrix(1, m)` and `Matrix(m, 1). Vector[row](n)` cause errors. If users do not want this level of rigor, then the easiest thing to do is to use only the `Matrix` declaration.

4. Comparison of norms in a symbolic setting. The matrix `A:=Matrix([[1,2],[3,x]])` has the infinity-norm `Norm(A)` equal to $3 + |x|$ whereas `Norm(A,2)` is already an expression too lengthy to reproduce here.
5. Working with matrices containing complex elements.
   First, notation: In linear algebra, I is commonly used for the identity matrix. This corresponds to the `eye` function in MATLAB. However, by default, Maple uses I for the imaginary unit, as seen in Section 89.2. We can, however, use I for an identity matrix by changing the imaginary unit to something else, say `_i`.

   ```
   > interface( imaginaryunit=_i):
   ```

   As the saying goes: An `_i` for an I and an I for an `eye`.

   Now we can calculate eigenvalues using notation similar to introductory textbooks.

   ```
   > A := <<1,2>|<-2,1>>; I := IdentityMatrix( 2 );
   p := Determinant ( x*I-A );
   ```

   $$A := \begin{bmatrix} 1 & -2 \\ 2 & 1 \end{bmatrix}, \quad I := \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad p := x^2 - 2\,x + 5.$$

   Solving $p = 0$, we obtain eigenvalues $1+2i, 1-2i$. With the above setting of `imaginaryunit`, Maple will print these values as `1+2 _i, 1-2 _i`, but we have translated back to standard mathematical i, where $i^2 = -1$.
6. Moore–Penrose inverse. Consider the following 3×2 matrix M, which contains a symbolic parameter a.

   $$M = \begin{bmatrix} 1 & 1 \\ a & a^2 \\ a^2 & a \end{bmatrix}.$$

   We compute its Moore–Penrose pseudoinverse and a proviso guaranteeing correctness by the command

   ```
   >(Mi, p):= MatrixInverse(M, method=pseudo, output=[inverse, proviso]);
   ```

   which assigns the 2×3 pseudoinverse to `Mi` and an expression which, if nonzero, guarantees that `Mi` is the correct (unique) Moore–Penrose pseudoinverse of M. Here we have

   $$Mi := \begin{bmatrix} \left(2+2\,a^3+a^2+a^4\right)^{-1} & -\dfrac{a^3+a^2+1}{a\,(a^5+a^4-a^3-a^2+2\,a-2)} & \dfrac{a^4+a^3+1}{a\,(a^5+a^4-a^3-a^2+2\,a-2)} \\ \left(2+2\,a^3+a^2+a^4\right)^{-1} & \dfrac{a^4+a^3+1}{a\,(a^5+a^4-a^3-a^2+2\,a-2)} & -\dfrac{a^3+a^2+1}{a\,(a^5+a^4-a^3-a^2+2\,a-2)} \end{bmatrix}$$

   and $p = a^2 - a$. Thus, if $a \neq 0$ and $a \neq 1$, the computed pseudoinverse is correct. By separate computations we find that the pseudoinverse of $M|_{a=0}$ is

   $$\begin{bmatrix} 1/2 & 0 & 0 \\ 1/2 & 0 & 0 \end{bmatrix}$$

   and that the pseudoinverse of $M|_{a=1}$ is

   $$\begin{bmatrix} 1/6 & 1/6 & 1/6 \\ 1/6 & 1/6 & 1/6 \end{bmatrix}$$

and *moreover that these are not special cases of the generic answer returned previously.* The Moore–Penrose inverse is one example of a linear algebra function that is *discontinuous*, even for square matrices. We give more examples below.

89.4 Arrays

Before describing Maple's `Array` structure, it is useful to say why Maple distinguishes between an `Array` and a `Vector` or `Matrix`, when other books and software systems do not. In linear algebra, two different types of operations are performed with vectors or matrices. The first type is described in Sections 89.2 and 89.3, and comprises operations derived from the mathematical structure of vector spaces. The other type comprises operations that treat vectors or matrices as data arrays; they manipulate the individual elements directly. As an example, consider dividing the elements of `Array` $[1, 3, 5]$ by the elements of $[7, 11, 13]$ to obtain $[1/7, 3/11, 5/13]$.

The distinction between the operations can be made in either of two places: in the name of the operation or the name of the object. In other words, we can overload either data objects or operators. Systems such as MATLAB choose to leave the data object unchanged, and define separate operators. Thus, in MATLAB the statements $[1, 3, 5]/[7, 11, 13]$ and $[1, 3, 5]./[7, 11, 13]$ are different because the operators are different. In contrast, Maple chooses to make the distinction in the data object, as will now be described.

Facts:

1. The Maple `Array` is a general data structure akin to arrays in other programming languages.
2. An array can have up to 63 indices and each index can lie in any integer range.
3. The description here only addresses the overlap between Maple `Array` and `Vector`.

Caution: A Maple `Array` might look the same as a vector or matrix when printed.

Commands:

1. Generation of arrays.
   - `Array`$([x_1, x_2, \ldots])$ Construct an array by listing its elements.
   - `Array( m..n )` Declare an empty one-dimensional array indexed from m to n.
   - `Array( v )` Use an existing `Vector` to generate an array.
   - `convert( v, Array )` Convert a `Vector v` into an `Array`. Similarly, a `Matrix` can be converted to an `Array`. See the help file for `rtable_options` for advanced methods to convert efficiently, in-place.
2. Operations (memory/stack limitations may restrict operations).
   - `a ∧ n` Raise each element of a to power n.
   - `a ∗ b, a + b, a − b` Multiply (add, subtract) elements of b by (to, from) elements of a.
   - `a / b` Divide elements of a by elements of b. Division by zero will produce `undefined` or `infinity` (or exceptions can be caught by user-set traps; see the help file for `Numeric_Events`).

Examples:

1. Array arithmetic.

```
> simplify( (Array([25,9,4])*Array(1..3,x->x∧2-1 )/Array(<5,3,2>\ ))∧(1/2));
```

$$[0, 3, 4]$$

2. Getting `Vectors` and `Arrays` to do the same thing.

```
> Transpose( map(x->x∗x,<1,2,3> )) - convert(Array( [1,2,3] )∧2, Vector);
```

$$[0, 0, 0]$$

89.5 Efficient Working with Vectors and Matrices

We point out here some aspects of the linear algebra package that are important for working with, and programming, Maple efficiently.

Facts:

1. Saving a copy of a matrix in Maple is different from many other computational packages. Consider this attempt to save a copy of matrix A in matrix B before altering A:

```
> A:=<< 1 | 2 | 3 >>: # Create a 1-by-3 matrix
> B:=A: # Store before modification
> A[1,1]:= -100: # Modify the first entry
> B;
```

$$[-100, 2, 3]$$

The reason for the matrix B changing along with A is that the statement `B:=A` equates the storage addresses of the two matrices, and thus both names point to the same location and any change to one will be reflected in the other. The intention of the user was to store a separate copy of the matrix A before modifying it. The way to do this is the following.

```
> A:=<< 1 | 2 | 3 >>: # Create the 1-by-3 matrix as before
> B:=Copy(A) :  # Store a copy before modification
> A[1,1]:= -100:  # Modify the first entry
> B; A;
                     [ 1,  2,  3]
                     [-100,   2,   3]
```

2. A puzzle will arise for a user who wants to construct a matrix by modifying an identity matrix, and tries `>  eye := IdentityMatrix(3,3);`

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

```
>  eye[1,2]:=4;
```

Error: invalid assignment

Maple by default stores an identity matrix in a compact form which has no room for additional elements. To obtain the desired action, proceed

```
> aye := IdentityMatrix(3,3,compact=false);
```

$$\begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

```
>  aye[1,2]:=4; aye
```

$$\begin{bmatrix} 1 & 4 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$$

3. Editing and Visualization. By default, the Maple interface writes out explicitly only matrices smaller than 10 × 10, and otherwise prints a summary of the matrix dimensions and datatype. If a user wishes to inspect a large matrix, there are several options. Submatrices of size 10 × 10 or less will print explicitly. Alternatively, a user can right-click on the output summary and select `Browse` from the menu. Elements can then be interactively edited and the edited matrix is saved on exit. If the edited matrix has been assigned to a name, the stored matrix will contain the edited elements. The Browse window also offers an image tab which uses greyscale or colors to visualize the structure of a matrix.
4. Programming with submatrices. In some computation systems, replacing explicit programming loops with submatrix operations gives efficiency gains. In addition to efficiency, many authors, for example [GV96], describe their algorithms using submatrices. In Maple, however, using submatrices does not increase efficiency because Maple makes a copy of each submatrix before executing any requested operation. As an example, the reader can enter the code below and execute it with his or her own matrices. Even without explicit timing, the speed differences will be clear for larger matrices.

   Suppose we wish to illustrate matrix multiplication as an explicit program, rather than use the built-in operation. This function calculates element by element:

```
mult1 := proc (A, B) local i, j, k, C, arow, acol, brow, bcol;
(arow, acol) := Dimension(A); (brow, bcol) := Dimension(B);
C := Matrix(arow, bcol);
for i to arow do
  for j to bcol do
    C[i, j] := add(A[i, k]*B[k, j], k = 1 .. acol);
    end do;
  end do;
return(C);
end proc;
```

   This one uses submatrix operations to multiply a row by a column:

```
mult2 := proc (A, B) local i, j, C, arow, acol, brow, bcol;
(arow, acol) := Dimension(A); (brow, bcol) := Dimension(B);
C := Matrix(arow, bcol);
for i to arow do
  for j to bcol do
    C[i, j] := A[i, 1 .. -1].B[1 .. -1, j]
    end do;
  end do;
return(C);
end proc;
```

89.6 Equation Solving and Matrix Factoring

Cautions:

1. If a matrix contains exact numerical entries, typically integers or rationals, then the material studied in introductory textbooks transfers to a computer algebra system without special considerations. However, if a matrix contains symbolic entries, then the fact that computations are completed without the user seeing the intermediate steps can lead to unexpected results.
2. Some of the most popular matrix functions are discontinuous when applied to matrices containing symbolic entries. Examples are given below.
3. Some algorithms taught to educate students about the concepts of linear algebra often turn out to be ill-advised in practice: computing the characteristic polynomial and then solving it to find eigenvalues, for example; using Gaussian elimination without pivoting on a matrix containing floating-point entries, for another.

Commands:

1. `LinearSolve( A, B )` The vector or matrix X satisfying $AX = B$. If B is a vector, so is X; otherwise, they are matrices.
2. `BackwardSubstitute( A, B ), ForwardSubstitute( A, B )` The vector or matrix X satisfying $AX = B$ when A is in upper or lower triangular (echelon) form, respectively.
3. `ReducedRowEchelonForm( A )` The reduced row-echelon form (RREF) of the matrix A. For matrices with symbolic entries, see the examples below for recommended usage.
4. `Rank( A )` The rank of the matrix A. Caution: If A has floating-point entries, see the section below on Numerical Linear Algebra. On the other hand, if A contains symbolic entries, then the rank may change discontinuously and the generic answer returned by `Rank` may be incorrect for some specializations of the parameters.
5. `NullSpace( A )` The nullspace (kernel) of the matrix A. Caution: If A has floating-point entries, see Section 89.9. Again, on the other hand, if A contains symbolic entries, the nullspace may change discontinuously and the generic answer returned by `NullSpace` may be incorrect for some specializations of the parameters.
6. `( P, L, U, R ) := LUDecomposition( A, method='RREF' )` The $PLUR$, or Turing, factors of the matrix A. See examples for usage.
7. `( P, L, U ) := LUDecomposition( A )` The PLU factors of a matrix A, when the RREF R is not needed. This is usually the case for a Turing factoring where R is guaranteed (or known a priori) to be I, the identity matrix, for all values of the parameters.
8. `( Q, R ) := QRDecomposition( A, fullspan )` The QR factors of the matrix A. The option `fullspan` ensures that Q is square.
9. `SingularValues( A )` See Section 89.9.
10. `ConditionNumber( A )` See Section 89.9.

Examples:

1. The need for Turing factoring.
   One of the strengths of Maple is computation with symbolic quantities. When standard linear algebra methods are applied to matrices containing symbolic entries, the user must be aware of new mathematical features that can arise. The main feature is the discontinuity of standard matrix functions, such as the reduced row-echelon form and the rank, both of which can be discontinuous. For example, the matrix

$$B = A - \lambda I = \begin{bmatrix} 7-\lambda & 4 \\ 6 & 2-\lambda \end{bmatrix}$$

has the reduced row-echelon form

$$\mathrm{ReducedRowEchelonForm}(B) = \begin{cases} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} & \lambda \neq -1, 10 \\[2ex] \begin{bmatrix} 1 & -4/3 \\ 0 & 0 \end{bmatrix} & \lambda = 10, \\[2ex] \begin{bmatrix} 1 & 1/2 \\ 0 & 0 \end{bmatrix} & \lambda = -1. \end{cases}$$

Notice that the function is discontinuous precisely at the interesting values of λ. Computer algebra systems in general, and Maple in particular, return "generic" results. Thus, in Maple, we have

```
> B := << 7-x | 4 >, < 6 | 2-x >>;
```

$$B := \begin{bmatrix} 7-x & 4 \\ 6 & 2-x \end{bmatrix},$$

```
> ReducedRowEchelonForm( B )
```

$$\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}.$$

This difficulty is discussed at length in [CJ92] and [CJ97]. The recommended solution is to use Turing factoring (generalized PLU decomposition) to obtain the reduced row-echelon form with provisos. Thus, for example,

```
> A := <<1|-2|3|sin(x)>,<1|4*cos(x)|3|3*sin(x)>,<-1|3|cos(x)-3|cos(x)>>;
```

$$A := \begin{bmatrix} 1 & -2 & 3 & \sin x \\ 1 & 4\cos x & 3 & 3\sin x \\ -1 & 3 & \cos x - 3 & \cos x \end{bmatrix}.$$

```
> ( P, L, U, R ) := LUDecomposition( A, method='RREF' ):
```

The generic reduced row-echelon form is then given by

$$R = \begin{bmatrix} 1 & 0 & 0 & (2\sin x\cos x - 3\sin x - 6\cos x - 3)/(2\cos x + 1) \\ 0 & 1 & 0 & \sin x/(2\cos x + 1) \\ 0 & 0 & 1 & (2\cos x + 1 + 2\sin x)/(2\cos x + 1) \end{bmatrix}$$

This shows a visible failure when $2\cos x + 1 = 0$, but the other discontinuity is invisible, and one requires the U factor from the Turing ($PLUR$) factors,

$$U = \begin{bmatrix} 1 & -2 & 3 \\ 0 & 4\cos x + 2 & 0 \\ 0 & 0 & \cos x \end{bmatrix}$$

to see that the case $\cos x = 0$ also causes failure. In both cases (meaning the cases $\cos x = 0$ and $2\cos x + 1 = 0$), the RREF must be recomputed to obtain the singular cases correctly.

2. QR factoring.

Maple does not offer column pivoting, so in pathological cases the factoring may not be unique, and will vary between software systems. For example,

```
> A := <<0,0>|<5,12>>: QRDecomposition( A, fullspan )
```

$$\begin{bmatrix} 5/13 & 12/13 \\ 12/13 & -5/13 \end{bmatrix}, \quad \begin{bmatrix} 0 & 13 \\ 0 & 0 \end{bmatrix}.$$

89.7 Eigenvalues and Eigenvectors

Facts:

1. In exact arithmetic, explicit expressions are not possible in general for the eigenvalues of a matrix of dimension 5 or higher.
2. When it has to, Maple represents polynomial roots (and, hence, eigenvalues) *implicitly* by the `RootOf` construct. Expressions containing `RootOf`s can be simplified and evaluated numerically.

Commands:

1. `Eigenvalues( A )` The eigenvalues of matrix A.
2. `Eigenvectors( A )` The eigenvalues and corresponding eigenvectors of A.
3. `CharacteristicPolynomial( A, 'x' )` The characteristic polynomial of A expressed using the variable x.
4. `JordanForm( A )` The Jordan form of the matrix A.

Examples:

1. Simple eigensystem computation.

```
> Eigenvectors( <<7,6>|<4,2>> );
```

$$\begin{bmatrix} -1 \\ 10 \end{bmatrix}, \begin{bmatrix} -1/2 & 4/3 \\ 1 & 1 \end{bmatrix}.$$

So the eigenvalues are -1 and 10 with the corresponding eigenvectors $[-1/2, 1]^T$ and $[4/3, 1]^T$.

2. A defective matrix.

If the matrix is defective, then by convention the matrix of "eigenvectors" returned by Maple contains one or more columns of zeros.

```
> Eigenvectors( <<1,0>|<1,1>> );
```

$$\begin{bmatrix} 1 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix}.$$

3. Larger systems.

For larger matrices, the eigenvectors will use the Maple `RootOf` construction. Consider

$$A := \begin{bmatrix} 3 & 1 & 7 & 1 \\ 5 & 6 & -3 & 5 \\ 3 & -1 & -1 & 0 \\ -1 & 5 & 1 & 5 \end{bmatrix}.$$

```
> ( L, V ) := Eigenvectors( A ):
```

The colon suppresses printing. The vector of eigenvalues is returned as

```
> L;
```

$$\begin{bmatrix} \texttt{RootOf}\left(\_Z^4 - 13\,\_Z^3 - 4\,\_Z^2 + 319\,\_Z - 386, \texttt{index} = 1\right) \\ \texttt{RootOf}\left(\_Z^4 - 13\,\_Z^3 - 4\,\_Z^2 + 319\,\_Z - 386, \texttt{index} = 2\right) \\ \texttt{RootOf}\left(\_Z^4 - 13\,\_Z^3 - 4\,\_Z^2 + 319\,\_Z - 386, \texttt{index} = 3\right) \\ \texttt{RootOf}\left(\_Z^4 - 13\,\_Z^3 - 4\,\_Z^2 + 319\,\_Z - 386, \texttt{index} = 4\right) \end{bmatrix}.$$

This, of course, simply reflects the characteristic polynomial:

```
> CharacteristicPolynomial( A, 'x' );
```

$$x^4 - 13x^3 - 4x^2 + 319x - 386$$

The `Eigenvalues` command solves a 4th degree characteristic polynomial explicitly in terms of radicals unless the option `implicit` is used.

4. Jordan form. *Caution*: As with the reduced row-echelon form, the Jordan form of a matrix containing symbolic elements can be discontinuous. For example, given

$$A = \begin{bmatrix} 1 & t \\ 0 & 1 \end{bmatrix},$$

```
> ( J, Q ) := JordanForm( A, output=[’J’,’Q’] );
```

$$J, Q := \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}, \begin{bmatrix} t & 0 \\ 0 & 1 \end{bmatrix}$$

with $A = QJQ^{-1}$. Note that Q is invertible precisely when $t \neq 0$. This gives a *proviso* on the correctness of the result: J will be the Jordan form of A only for $t \neq 0$, which we see is the generic case returned by Maple.

Caution: Exact computation has its limitations, even without symbolic entries. If we ask for the Jordan form of the matrix

$$B = \begin{bmatrix} -1 & 4 & -1 & -14 & 20 & -8 \\ 4 & -5 & -63 & 203 & -217 & 78 \\ -1 & -63 & 403 & -893 & 834 & -280 \\ -14 & 203 & -893 & 1703 & -1469 & 470 \\ 20 & -217 & 834 & -1469 & 1204 & -372 \\ -8 & 78 & -280 & 470 & -372 & 112 \end{bmatrix},$$

a relatively modest 6×6 matrix with a triple eigenvalue 0, then the transformation matrix Q as produced by Maple has entries over 35,000 characters long. Some scheme of compression or large expression management is thereby mandated.

89.8 Linear Algebra with Modular Arithmetic

There is a subpackage, `LinearAlgebra[Modular]`, designed for programmatic use, that offers access to modular arithmetic with matrices and vectors.

Facts:

1. The subpackage can be loaded by issuing the command
   `> with( LinearAlgebra[Modular] );` which gives access to the commands

```
[AddMultiple, Adjoint, BackwardSubstitute, Basis, Characteristic
Polynomial, ChineseRemainder, Copy, Create, Determinant, Fill,
ForwardSubstitute, Identity, Inverse, LUApply, LUDecomposition,
LinIntSolve, MatBasis, MatGcd, Mod, Multiply, Permute, Random,
Rank, RankProfile, RowEchelonTransform, RowReduce, Swap,
Transpose,  ZigZag]
```

2. Arithmetic can be done modulo a prime p or, in some cases, a composite modulus m.
3. The relevant matrix and vector datatypes are `integer[4]`, `integer[8]`, `integer[]`, and `float[8]`. Use of the correct datatype can improve efficiency.

Examples:

```
> p := 13;
> A := Mod( p, Matrix([[1,2,3],[4,5,6],[7,8,-9]]), integer[4] );
```

$$\begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 4 \end{bmatrix},$$

```
> Mod( p, MatrixInverse( A ), integer[4] );
```

$$\begin{bmatrix} 12 & 8 & 5 \\ 0 & 11 & 3 \\ 5 & 3 & 5 \end{bmatrix}$$

Cautions:

1. This is not to be confused with the `mod` utilities, which together with the inert `Inverse` command can also be used to calculate inverses in a modular way.
2. One must always specify the datatype in `Modular` commands, or a cryptic error message will be generated.

89.9 Numerical Linear Algebra in Maple

The previous sections have covered the use of Maple for exact computations of the types met during a standard first course on linear algebra. However, in addition to exact computation, Maple offers a variety of floating-point numerical linear algebra support.

Facts:

1. Maple can compute with either "hardware floats" or "software floats."
2. A hardware float is IEEE double precision, with a mantissa of (approximately) 15 decimal digits.
3. A software float has a mantissa whose length is set by the Maple variable `Digits`.

Cautions:

1. If an integer is typed with a decimal point, then Maple treats it as a software float.
2. Software floats are significantly slower that hardware floats, even for the same precision.

Commands:

1. `Matrix( n, m, datatype=float[8] )` An $n \times m$ matrix of hardware floats (initialization data not shown). The elements must be real numbers. The 8 refers to the number of bytes used to store the floating point real number.
2. `Matrix( n, m, datatype=complex(float[8] ))` An $n \times m$ matrix of hardware floats, including complex hardware floats. A complex hardware float takes two 8-byte storage locations.
3. `Matrix( n, m, datatype=sfloat )` An $n \times m$ matrix of software floats. The entries must be real and the precision is determined by the value of `Digits`.
4. `Matrix( n, m, datatype=complex(sfloat) )` As before with complex software floats.
5. `Matrix( n, m, shape=symmetric )` A matrix declared to be symmetric. Maple can take advantage of shape declarations such as this.

Examples:

1. A characteristic surprise.
   When asked to compute the characteristic polynomial of a floating-point matrix, Maple first computes eigenvalues (by a good numerical method) and then presents the characteristic

polynomial in factored form, with good approximate roots. Thus,

```
> A:= Matrix( 2, 2, [[666,667],[665,666]],datatype=float[8]):
> CharacteristicPolynomial( A, 'x' )
```

$$(x - 1331.99924924882612 - 0.0\,i)\,(x - 0.000750751173882235889 - 0.0\,i)\,.$$

Notice the signed zero in the imaginary part; though the roots in this case are real, approximate computation of the eigenvalues of a nonsymmetric matrix takes place over the complex numbers. (n.b.: The output above has been edited for clarity.)

2. Symmetric matrices.
   If Maple knows that a matrix is symmetric, then it uses appropriate routines. Without the symmetric declaration, the calculation is

   ```
   > Eigenvalues( Matrix( 2, 2, [[1,3],[3,4]], datatype=float[8]) );
   ```

   $$\begin{bmatrix} -0.854101966249684707 + 0.0\,i \\ 5.85410196624968470 + 0.0\,i \end{bmatrix}.$$

   With the declaration, the computation is

   ```
   > Eigenvalues( Matrix( 2, 2, [[1,3],[3,4]], shape=symmetric,
    datatype=float[8]) );
   ```

   $$\begin{bmatrix} -0.854101966249684818 \\ 5.85410196624968470 \end{bmatrix}.$$

   Cautions: Use of the `shape=symmetric` declaration will force Maple to treat the matrix as being symmetric, even if it is not.
3. Printing of hardware floats.
   Maple prints hardware floating-point data as 18-digit numbers. This does not imply that all 18 digits are correct; Maple prints the hardware floats this way so that a cycle of converting from binary to decimal and back to binary will return to exactly the starting binary floating-point number. Notice in the previous example that the last three digits differ between the two function calls. In fact, neither set of digits is correct, as a calculation in software floats with higher precision shows:

   ```
   > Digits := 30: Eigenvalues( Matrix( 2, 2, [[1,3],[3,4]], \
       datatype=sfloat, shape=symmetric ) );
   ```

   $$\begin{bmatrix} -0.854101966249684544613760503093 \\ 5.85410196624968454461376050310 \end{bmatrix}.$$

4. NullSpace. Consider

   ```
   > B := Matrix( 2, 2, [[666,667],[665,666]] ): A := Transpose(B).B;
   ```

   We make a floating-point version of A by

   ```
   > Af := Matrix( A, datatype=float[8] );
   ```

   and then take the `NullSpace` of both `A` and `Af`. The nullspace of `A` is correctly returned as the empty set — A is not singular (in fact, its determinant is 1). The nullspace of `Af` is correctly returned as

   $$\left\{ \begin{bmatrix} -0.707637442412755612 \\ 0.706575721416702662 \end{bmatrix} \right\}.$$

   The answers are different — quite different — even though the matrices differ only in datatype. The surprising thing is that both answers are *correct*: Maple is doing the right thing in each case. See [Cor93] for a detailed explanation, but note that `Af` times the vector in the reported nullspace is about $3.17 \cdot 10^{-13}$ times the 2-norm of `Af`.

5. Approximate Jordan form (not!).[1]
   As noted previously, the Jordan form is discontinuous as a function of the entries of the matrix. This means that rounding errors may cause the computed Jordan form of a matrix with floating-point entries to be incorrect, and for this reason Maple refuses to compute the Jordan form of such a matrix.
6. Conditioning of eigenvalues.
   To explore Maple's facilities for the conditioning of the unsymmetric matrix eigenproblem, consider the matrix "gallery(3)" from MATLAB.

```
> A := Matrix( [[-149,-50,-154], [537,180,546], [-27,-9,-25]] ):
```

   The Maple command `EigenConditionNumbers` computes estimates for the reciprocal condition numbers of each eigenvalue, and estimates for the reciprocal condition numbers of the computed eigenvectors as well. At this time, there are no built-in facilities for the computation of the sensitivity of arbitrary invariant subspaces.

```
> E,V,rconds,rvecconds := EigenConditionNumbers( A, output=
['values', 'vectors','conditionvalues','conditionvectors'] ):
> seq( 1/rconds[i], i=1..3 );
                                417.6482708, 349.7497543, 117.2018824
```

   A separate computation using the definition of the condition number of an eigentriplet $(\mathbf{y}^*, \lambda, \mathbf{x})$ (see Chapter 21) as

$$C_\lambda = \frac{\|\mathbf{y}^*\|_\infty \|\mathbf{x}\|_\infty}{|\mathbf{y}^* \cdot \mathbf{x}|}$$

   gives exact condition numbers (in the infinity norm) for the eigenvalues 1, 2, 3 as 399, 252, and 147. We see that the estimates produced by `EigenConditionNumbers` are of the right order of magnitude.

89.10 Canonical Forms

There are several canonical forms in Maple: Jordan form, Smith form, Hermite form, and Frobenius form, to name a few. In this section, we talk only about the Smith form (defined in Section 6.6 and Section 32.2).

Commands:

1. `SmithForm( B, output=['S','U','V'] )` Smith form of B.

Examples:

The Smith form of

$$B = \begin{bmatrix} 0 & -4y^2 & 4y & -1 \\ -4y^2 & 4y & -1 & 0 \\ 4y & -1 & 4\left(2y^2-2\right)y & 4\left(y^2-1\right)^2 y^2 - 2\,y^2 + 2 \\ -1 & 0 & 4\left(y^2-1\right)^2 y^2 - 2\,y^2 + 2 & -4\left(y^2-1\right)^2 y \end{bmatrix}$$

---

[1] An out-of-date, humorous reference.

is

$$S = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1/4\left(2y^2-1\right)^2 & 0 \\ 0 & 0 & 0 & (1/64)\left(2\,y^2-1\right)^6 \end{bmatrix}.$$

Maple also returns two unimodular (over the domain $Q[y]$) matrices U and V for which $A = U.S.V$.

89.11 Structured Matrices

Facts:

1. Computer algebra systems are particularly useful for computations with structured matrices.
2. User-defined structures may be programmed using *index functions*. See the help pages for details.
3. Examples of built-in structures include *symmetric*, *skew-symmetric*, *Hermitian*, *Vandermonde*, and *Circulant* matrices.

Examples:

Generalized Companion Matrices. Maple can deal with several kinds of generalized companion matrices. A generalized companion matrix[2] *pencil* of a polynomial $p(x)$ is a pair of matrices C_0, C_1 such that $\det(xC_1 - C_0) = 0$ precisely when $p(x) = 0$. Usually, in fact, $\det(xC_1 - C_0) = p(x)$, though in some definitions proportionality is all that is needed. In the case $C_1 = I$, the identity matrix, we have $C_0 = C(p(x))$ is *the companion matrix* of $p(x)$. MATLAB's `roots` function computes roots of polynomials by first computing the eigenvalues of the companion matrix, a venerable procedure only recently proved stable.

The generalizations allow direct use of alternative polynomial bases, such as the Chebyshev polynomials, Lagrange polynomials, Bernstein (Bézier) polynomials, and many more. Further, the generalizations allow the construction of generalized companion matrix pencils for *matrix polynomials*, allowing one to easily solve *nonlinear eigenvalue problems.*

We give three examples below.

If $p := 3+2x+x^2$, then `CompanionMatrix( p, x )` produces "the" (standard) companion matrix (also called *Frobenius form* companion matrix):

$$\begin{bmatrix} 0 & -3 \\ 1 & -2 \end{bmatrix}$$

and it is easy to see that $\det(tI - C) = p(t)$. If instead

$$p := B_0^3(x) + 2B_1^3(x) + 3B_2^3(x) + 4B_3^3(x)$$

where $B_k^n(x) = \binom{n}{k}(1-x)^{n-k}(x+1)^k/2^n$ is the kth Bernstein (Bézier) polynomial of degree n on the interval $-1 \le x \le 1$, then `CompanionMatrix( p, x )` produces the pencil (note that this is not in Frobenius form)

$$C_0 = \begin{bmatrix} -3/2 & 0 & -4 \\ 1/2 & -1/2 & -8 \\ 0 & 1/2 & -\dfrac{52}{3} \end{bmatrix}$$

---

[2] Sometimes known as "colleague" or "comrade" matrices, an unfortunate terminology that inhibits keyword search.

$$C_1 = \begin{bmatrix} 3/2 & 0 & -4 \\ 1/2 & 1/2 & -8 \\ 0 & 1/2 & -\frac{20}{3} \end{bmatrix}$$

(from a formula by Jonsson and Vavasis [JV05] and independently by Winkler [Win04]), and we have $p(x) = \det(xC_1 - C_0)$. Note that the program does *not* change the basis of the polynomial $p(x)$ of Eq. (89.9) to the monomial basis (it turns out that $p(x) = 20 + 12x$ in the monomial basis, in this case: note that C_1 is singular). It is well known that changing polynomial bases can be ill-conditioned, and this is why the routine avoids making the change.

Next, if we choose nodes $[-1, -1/3, 1/3, 1]$ and look at the degree 3 polynomial taking the values $[1, -1, 1, -1]$ on these four nodes, then `CompanionMatrix( values, nodes )` gives C_0 and C_1 where C_1 is the 5×5 identity matrix with the $(5, 5)$ entry replaced by 0, and

$$C_0 = \begin{bmatrix} 1 & 0 & 0 & 0 & -1 \\ 0 & 1/3 & 0 & 0 & 1 \\ 0 & 0 & -1/3 & 0 & -1 \\ 0 & 0 & 0 & -1 & 1 \\ -\frac{9}{16} & \frac{27}{16} & -\frac{27}{16} & \frac{9}{16} & 0 \end{bmatrix}.$$

We have that $\det(tC_1 - C_0)$ is of degree 3 (in spite of these being 5×5 matrices), and that this polynomial takes on the desired values ± 1 at the nodes. Therefore, the finite eigenvalues of this pencil are the roots of the given polynomial. See [CW04] and [Cor04], for example, for more information.

Finally, consider the nonlinear eigenvalue problem below: find the values of x such that the matrix C with $C_{ij} = T_0(x)/(i+j+1) + T_1(x)/(i+j+2) + T_2(x)/(i+j+3)$ is singular. Here $T_k(x)$ means the kth Chebyshev polynomial, $T_k(x) = \cos(k \cos^{-1}(x))$. We issue the command

```
> ( C0, C1 ) := CompanionMatrix( C, x );
```

from which we find

$$C0 = \begin{bmatrix} 0 & 0 & 0 & -2/15 & -1/12 & -\frac{2}{35} \\ 0 & 0 & 0 & -1/12 & -\frac{2}{35} & -1/24 \\ 0 & 0 & 0 & -\frac{2}{35} & -1/24 & -\frac{2}{63} \\ 1 & 0 & 0 & -1/4 & -1/5 & -1/6 \\ 0 & 1 & 0 & -1/5 & -1/6 & -1/7 \\ 0 & 0 & 1 & -1/6 & -1/7 & -1/8 \end{bmatrix}$$

and

$$C1 = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2/5 & 1/3 & 2/7 \\ 0 & 0 & 0 & 1/3 & 2/7 & 1/4 \\ 0 & 0 & 0 & 2/7 & 1/4 & 2/9 \end{bmatrix}.$$

This uses a formula from [Goo61], extended to matrix polynomials. The six generalized eigenvalues of this pencil include, for example, one near to $-0.6854 + 1.909i$. Substituting this eigenvalue in for x in C yields a three-by-three matrix with ratio of smallest to largest singular values $\sigma_3/\sigma_1 \approx 1.7 \cdot 10^{-15}$. This is effectively singular and, thus, we have found the solutions to the nonlinear eigenvalue problem. Again note that the generalized companion matrix is not in Frobenius standard form, and that this process works for a variety of bases, including the Lagrange basis.

Circulant matrices and Vandermonde matrices.

```
> A := Matrix( 3, 3, shape=Circulant[a,b,c] );
```

$$\begin{bmatrix} a & b & c \\ c & a & b \\ b & c & a \end{bmatrix},$$

```
> F3 := Matrix( 3,3,shape=Vandermonde[[1,exp(2*Pi*I/3),exp(4*Pi*I/3)]] );
```

$$\begin{bmatrix} 1 & 1 & 1 \\ 1 & -1/2 + 1/2\,i\sqrt{3} & \left(-1/2 + 1/2\,i\sqrt{3}\right)^2 \\ 1 & -1/2 - 1/2\,i\sqrt{3} & \left(-1/2 - 1/2\,i\sqrt{3}\right)^2 \end{bmatrix}.$$

It is easy to see that the `F3` matrix diagonalizes the circulant matrix `A`.

Toeplitz and Hankel matrices. These can be constructed by calling `ToeplitzMatrix` and `HankelMatrix`, or by direct use of the `shape` option of the `Matrix` constructor.

```
> T := ToeplitzMatrix( [a,b,c,d,e,f,g] );
> T := Matrix( 4,4,shape=Toeplitz[false,Vector(7,[a,b,c,d,e,f,g])] );
```

both yield a matrix that looks like

$$\begin{bmatrix} d & c & b & a \\ e & d & c & b \\ f & e & d & c \\ g & f & e & d \end{bmatrix},$$

though in the second case only 7 storage locations are used, whereas 16 are used in the first. This economy may be useful for larger matrices. The shape constructor for Toeplitz also takes a Boolean argument `true`, meaning symmetric.

Both Hankel and Toeplitz matrices may be specified with an indexed symbol for the entries:

`> H := Matrix( 4, 4, shape=Hankel[a] );` yields

$$\begin{bmatrix} a_1 & a_2 & a_3 & a_4 \\ a_2 & a_3 & a_4 & a_5 \\ a_3 & a_4 & a_5 & a_6 \\ a_4 & a_5 & a_6 & a_7 \end{bmatrix}.$$

89.12 Functions of Matrices

The exponential of the matrix A is computed in the `MatrixExponential` command of Maple by *polynomial interpolation* (see Section 17.1) of the exponential at each of the eigenvalues of A, including multiplicities. In an exact computation context, this method is not so "dubious" [MV78, Lab97]. This approach is also used by the general `MatrixFunction` command.

Examples:

```
> A := Matrix( 3, 3, [[-7,-4,-3],[10,6,4],[6,3,3]] ):
> MatrixExponential( A );
```

$$\begin{bmatrix} 6 - 7\,e^1 & 3 - 4\,e^1 & 2 - 3\,e^1 \\ 10\,e^1 - 6 & -3 + 6\,e^1 & -2 + 4\,e^1 \\ 6\,e^1 - 6 & -3 + 3\,e^1 & -2 + 3\,e^1 \end{bmatrix} \tag{89.1}$$

Now a square root: `> MatrixFunction( A, sqrt(x), x ):`

$$\begin{bmatrix} -6 & -7/2 & -5/2 \\ 8 & 5 & 3 \\ 6 & 3 & 3 \end{bmatrix} \tag{89.2}$$

Another matrix square root example, for a matrix close to one that has no square root:

```
> A := Matrix( 2, 2, [[epsilon∧2, 1], [0, delta∧2] ] ):
> S := MatrixFunction( A, sqrt(x), x ):
> simplify( S ) assuming positive;
```

$$\begin{bmatrix} \epsilon & \dfrac{1}{\epsilon+\delta} \\ 0 & \delta \end{bmatrix} \tag{89.3}$$

If ϵ and δ both approach zero, we see that the square root has an entry that approaches infinity. Calling `MatrixFunction` on the above matrix with $\epsilon = \delta = 0$ yields an error message, `Matrix function x∧(1/2) is not defined for this Matrix`, which is correct.

Now for the matrix logarithm.

```
> Pascal := Matrix( 4, 4, (i,j)->binomial(j-1,i-1) );
```

$$\begin{bmatrix} 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{89.4}$$

```
> MatrixFunction( Pascal, log(x), x );
```

$$\begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 3 \\ 0 & 0 & 0 & 0 \end{bmatrix} \tag{89.5}$$

Now a function not covered in Chapter 17, instead of redoing the sine and cosine examples:

```
> A := Matrix( 2, 2, [[-1/5, 1], [0, -1/5]] ):
> W := MatrixFunction( A, LambertW(-1,x), x );
```

$$W := \begin{bmatrix} \mathrm{LambertW}(-1,-1/5) & -5\,\dfrac{\mathrm{LambertW}\,(-1,-1/5)}{1+\mathrm{LambertW}\,(-1,-1/5)} \\ 0 & \mathrm{LambertW}\,(-1,-1/5) \end{bmatrix} \tag{89.6}$$

```
> evalf( W );
```

$$\begin{bmatrix} -2.542641358 & -8.241194055 \\ 0.0 & -2.542641358 \end{bmatrix} \tag{89.7}$$

That matrix satisfies $W\exp(W) = A$, and is a *primary matrix function*. See [CGH$^+$96] for more details about the Lambert W function, and [CDH07] for more details on matrix W.

Now the matrix sign function (cf. Section 17.7). Consider

```
> Pascal2 := Matrix( 4, 4, (i,j)->(-1)∧(i-1)*binomial(j-1,i-1) );
```

$$\begin{bmatrix} 1 & 1 & 1 & 1 \\ 0 & -1 & -2 & -3 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 0 & -1 \end{bmatrix}. \tag{89.8}$$

Then we compute the matrix sign function of this matrix by
`> S := MatrixFunction( Pascal2, csgn(z), z ):` which turns out to be the same matrix (`Pascal2`).

Note: The complex "sign" function we use here is not the usual complex sign function for scalars

$$\operatorname{signum}(re^{i\theta}) := e^{i\theta},$$

but rather (as desired for the definition of the matrix sign function)

$$\operatorname{csgn}(z) = \begin{cases} 1 & \text{if } \operatorname{Re}(z) > 0 \\ -1 & \text{if } \operatorname{Re}(z) < 0 \\ \operatorname{signum}(\operatorname{Im}(z)) & \text{if } \operatorname{Re}(z) = 0 \end{cases}.$$

This has the side effect of making the function defined even when the input matrix has purely imaginary eigenvalues. The signum and `csgn` of 0 are both 0, by default, but can be specified differently if desired.

Cautions:

1. Further, it is not the `sign` function in Maple, which is a different function entirely: That function (`sign`) returns the sign of the leading coefficient of the polynomial input to `sign`.
2. (In general) This general approach to computing matrix functions can be slow for large exact or symbolic matrices (because manipulation of symbolic representations of the eigenvalues using `RootOf`, typically encountered for $n \geq 5$, can be expensive), and on the other hand can be unstable for floating-point matrices, as is well known, especially those with nearly multiple eigenvalues. However, for small or for structured matrices this approach can be very useful and can give insight.

89.13 Matrix Stability

As defined in Chapter 26, a matrix is (negative) *stable* if all its eigenvalues are in the left half-plane (in this section, "stable" means "negative stable"). In Maple, one may test this by direct computation of the eigenvalues (if the entries of the matrix are numeric) and this is likely faster and more accurate than any purely rational operation based test such as the Hurwitz criterion. If, however, the matrix contains symbolic entries, then one usually wishes to know for what values of the parameters the matrix is stable. We may obtain conditions on these parameters by using the `Hurwitz` command of the `PolynomialTools` package on the characteristic polynomial.

Examples:

Negative of `gallery(3)` from MATLAB.

```
> A := -Matrix( [[-149,-50,-154], [537,180,546], [-27,-9,-25]] ):
> E := Matrix( [[130, -390, 0], [43, -129, 0], [133,-399,0]] ):
> AtE := A - t*E;
```

$$\begin{bmatrix} 149-130\,t & 50+390\,t & 154 \\ -537-43\,t & -180+129\,t & -546 \\ 27-133\,t & 9+399\,t & 25 \end{bmatrix} \tag{89.9}$$

For which t is that matrix stable?

```
> p := CharacteristicPolynomial( AtE, lambda );
> PolynomialTools[Hurwitz]( p, lambda, 's', 'g' );
```

This command returns "FAIL," meaning that it cannot tell whether p is stable or not; this is only to be expected as t has not yet been specified. However, according to the documentation, all coefficients of λ returned in `s` must be positive in order for p to be stable. The coefficients returned are

$$\left[\frac{\lambda}{6+t}, 1/4\,\frac{(6+t)^2\,\lambda}{15+433453\,t+123128\,t^2}, \frac{\left(60+1733812\,t+492512\,t^2\right)\lambda}{(6+t)\,(6+1221271\,t)}\right] \tag{89.10}$$

and analysis (not given here) shows that these are all positive if and only if $t > -6/1221271$.

Acknowledgments

Many people have contributed to linear algebra in Maple, for many years. Dave Hare and David Linder deserve particular credit, especially for the LinearAlgebra package and its connections to CLAPACK, and have also greatly helped our understanding of the best way to use this package. We are grateful to Dave Linder and to Jürgen Gerhard for comments on early drafts of this chapter.

90.1 Introduction

About *Mathematica*

Mathematica is a comprehensive software system for doing symbolic and numerical calculations, creating graphics, animations, and dynamic interfaces, writing programs, and preparing documents:

- The heart of *Mathematica* is its broad collection of tools for symbolic and exact mathematics, but numerical methods also form an essential part of the system.
- *Mathematica* is known for its high-quality graphics and its ability to create advanced dynamic interfaces.
- The system is also a powerful programming language, supporting both traditional procedural techniques and functional, rule-based, and recursive programming.
- In addition, *Mathematica* is an environment for preparing high-quality documents.

The first version of *Mathematica* was released in 1988. *Mathematica* now contains over 4000 commands and is one of the largest single application programs ever developed. *Mathematica* is a product of Wolfram Research, Inc. The founder, president, and CEO of Wolfram Research is Stephen Wolfram.

Mathematica contains two main parts: the **kernel** and the **front end**. The kernel does the computations. For example, the implementation of the `Integrate` command comprises about 500 pages of *Mathematica* code and 600 pages of C code. The front end is a user interface that takes care of the communication between the user and the kernel. In addition, there are **packages** that supplement the kernel; packages have to be loaded as needed.

The most common type of user interface is based on interactive documents known as **notebooks**. *Mathematica* is often used like an advanced calculator for a moment's need, in which case a notebook is simply an interface to write the commands and read the results. However, often a notebook grows to be a useful document that you will save or print or use in a presentation.

Notebooks consist of **cells**. Each cell is indicated with a **cell bracket** at the right side of the notebook. Cells are grouped in various ways so as to form a hierarchical structure. For example, each input is in a cell, each output is in a cell, and each input−output pair forms a higher-level cell.

About this Chapter

In this chapter, we cover the essentials of doing linear algebra calculations with *Mathematica* 8. The chapter covers many of the topics of the handbook done via *Mathematica*, and the reader should consult the relevant chapter for further information.

Many commands are demonstrated in the Examples subsections, but note that the examples are very simple. Indeed, the aim of these examples is only to show how the commands are used and what kind of result we get in simple cases. We do not demonstrate the full power and every feature of the commands.

The Appendix contains a short introduction to the use of *Mathematica*. There we also refer to some books, documents, and help material where you can find further information about *Mathematica* and linear algebra with *Mathematica*.

As in *Mathematica* notebooks, in this chapter *Mathematica* commands and their arguments are in boldface while outputs are in a plain font. *Mathematica* normally shows the output below the input, but here, in order to save space, we mostly show the output next to the input.

Matrices are traditionally denoted by capital letters like A or M. However, in *Mathematica* we have the general advice that all user-defined names should begin with lower-case letters so that they do not conflict with the built-in names, which always begin with an upper-case letter. We follow this advice and mainly use the lower-case letter **`m`** for matrices. In principle, we could use most upper-case letters, but note that the letters **`C`**, **`D`**, **`E`**, **`I`**, **`N`**, and **`O`** are reserved names in *Mathematica* and they cannot be used as user-defined names.

90.2 Vectors

Commands

Vectors in *Mathematica* are lists. In Section 90.3 we will see that matrices are lists of lists, each sublist being a row of the matrix. Note that *Mathematica* does not distinguish between row and column vectors. Indeed, when we compute with vectors and matrices, in most cases it is evident for *Mathematica* how an expression has to be calculated. Only in some rare cases do we need to be careful and write an expression in such a way that *Mathematica* understands the expression in the correct way. One of these cases is the multiplication of a column vector by a row vector; this has to be done with **`KroneckerProduct`** (see Command 4 below). For sparse vectors, see Command 90.3.5.

1. Vectors in *Mathematica*:
   - **`v = {a, b, c, ... }`** A vector **`v`** with elements **`a`**, **`b`**, **`c`**, **`...`**.
   - **`MatrixForm[v]`** Display vector **`v`** in a column form.
   - **`Length[v]`** The number of elements of vector **`v`**.
   - **`VectorQ[v]`** Test whether **`v`** is a vector.
2. Generation of vectors:
   - **`Range[n`**$_1$**`]`** Create the vector (1, 2, ..., n_1). With **`Range[n`**$_0$**`, n`**$_1$`]` we get the

vector (n_0, n_0 + 1, . . ., n_1) and with **Range[n_0, n_1, d]** the vector (n_0, n_0 + **d**, n_0 + 2**d**, . . ., n_1).

- **Table[expr, {i, n_1}]** Create a vector by giving **i** the values 1, 2, . . ., n_1 in **expr**. If the iteration specification is {**i, n_0, n_1**}, then **i** gets the values n_0, n_0 + 1, . . ., n_1, and for {**i, n_0, n_1, d**}**]**, the values of **i** are between n_0 and n_1 in steps of **d**. For {n_1}, simply n_1 copies of **expr** are taken.
- **Array[f, n_1]** Create the n_1 vector (**f[1]**, . . ., **f[n_1]**). With **Array[f, n_1, n_0]** we get the n_1 vector (**f[n_0]**, . . ., **f[$n_0 + n_1 - 1$]**).
- **ConstantArray[c, n]** Create the **n** vector (**c**, . . ., **c**).
- **UnitVector[n, k]** Create the **n**-dimensional unit vector in the **k**th direction.

3. Arithmetic of vectors:

- **a v** Multiply vector **v** with scalar **a**.
- **u + v** Add two vectors.
- **u v** Multiply the corresponding elements of two vectors and form a vector from the products (there is a space between **u** and **v**); for an inner product, write **u.v**.
- **u/v** Divide the corresponding elements of two vectors.
- **v^p** Calculate the **p**th power of each element of a vector.
- **a^v** Generate a vector by calculating the powers of scalar **a** that are given in vector **v**.

4. Products of two vectors:

- **u.v** or **Dot[u, v]** The inner product of two vectors of the same size.
- **KroneckerProduct[u, v]** The outer product (a matrix) of vectors **u** and **v**.
- **Cross[u, v]** The cross product of two vectors.

5. Sums and products of elements of vectors:

- **Total[v]** The sum of the elements of a vector.
- **Apply[Times, v]** The product of the elements of a vector.

6. Norms of vectors:

- **Norm[v]** or **Norm[v, 2]** or **Sqrt[v.Conjugate[v]]** The 2-norm (or Euclidean norm).
- **Norm[v, 1]** or **Total[Abs[v]]** The 1-norm.
- **Norm[v, ∞]** or **Max[Abs[v]]** The ∞-norm.
- **Norm[v, p]** or **Total[Abs[v]^p]^(1/p)** The **p**-norm; **p** is a number in [1, ∞).

7. Distances between vectors:

- **EuclideanDistance[u, v]** or **Norm[u − v]**
- **SquaredEuclideanDistance[u, v]** or **Norm[u - v]^2**
- **ChessboardDistance[u, v]** or **Max[Abs[u − v]]**
- **ManhattanDistance[u, v]** or **Total[Abs[u − v]]**
- **CanberraDistance[u, v]** or **Total[Abs[u − v]/(Abs[u] + Abs[v])]**
- **BrayCurtisDistance[u, v]** or **Total[Abs[u − v]]/Total[Abs[u + v]]**
- **HammingDistance[u, v]** The number of elements whose values disagree in **u** and **v**.

8. Orthogonalization of vectors, etc.:

- **`Orthogonalize[{u, v, ... }]`** Generate an orthonormal set from the given vectors.
- **`Projection[u, v]`** The orthogonal projection of **`u`** onto **`v`**.
- **`Normalize[v]`** The unit vector in the direction of **`v`**
- **`VectorAngle[u, v]`** The angle between the vectors **`u`** and **`v`**.

9. Taking a part of a vector (the output is the corresponding part):

- **`v[[i]]`** Take element **`i`**.
- **`v[[{i, j, ... }]]`** Take elements **`i`**, **`j`**, ...
- **`v[[i ;; j]]`** Take elements **`i`** through **`j`**.
- **`v[[;; j]]`** Take the first **`j`** elements.
- **`v[[;; -j]]`** Take the elements from the beginning to the **`j`**th element from the end.
- **`v[[i ;;]]`** Take elements from **`i`** to the end.
- **`v[[-i ;;]]`** Take the last **`i`** elements.
- The above commands can also be used to set new values for the corresponding elements; for example, **`v[[i]] = a`**.
- **`First[v]`**, **`Last[v]`** Take the first/last element.
- **`Rest[v]`**, **`Most[v]`** Drop the first/last element.
- **`Take[v, n]`**, **`Take[v, -n]`**, **`Take[v, {n1, n2}]`** Take the first **`n`** elements/the last **`n`** elements/elements $\mathtt{n}_1$, . . ., $\mathtt{n}_2$.
- **`Drop[v, n]`**, **`Drop[v, -n]`**, **`Drop[v, {n1, n2}]`** Drop the first **`n`** elements/the last **`n`** elements/elements $\mathtt{n}_1$, . . ., $\mathtt{n}_2$.
- **`Delete[v, i]`**, **`Delete[v, {{i}, {j}, ... }]`** Delete element **`i`**/elements **`i`**, **`j`**, ...

10. Adding elements into vectors (output is the resulting vector):

- **`Prepend[v, a]`**, **`Append[v, a]`** Insert element **`a`** at the beginning/end of a vector.
- **`PrependTo[v, a]`**, **`AppendTo[v, a]`** Insert element **`a`** at the beginning/end of a vector and reset **`v`** to the result.
- **`Insert[v, a, i]`** Insert element **`a`** between elements **`i`** − 1 and **`i`**.

Examples

1. Vectors in *Mathematica*.

`v = {4,2,3}` {4,2,3}

`MatrixForm[v]`
$$\begin{pmatrix} 4 \\ 2 \\ 3 \end{pmatrix}$$

`Length[v]` 3

`VectorQ[v]` True

2. Generation of vectors. **`Range`** is nice for forming lists of integers or reals:

`Range[10]` `{1,2,3,4,5,6,7,8,9,10}`

`Range[0,10,2]` `{0,2,4,6,8,10}`

`Range[1.5,2,0.1]` `{1.5,1.6,1.7,1.8,1.9,2.}`

`Table` is one of the most useful commands in *Mathematica*:

`Table[x^i,{i,5}]` $\{x,x^2,x^3,x^4,x^5\}$

`Table[D[Sin[x^n],x],{n,3}]` $\{\mathrm{Cos}[x],2x\mathrm{Cos}[x^2],3x^2\mathrm{Cos}[x^3]\}$

`Array` is nice for forming lists of indexed variables:

`Array[x,5]` `{x[1],x[2],x[3],x[4],x[5]}`

`Array[x,5,0]` `{x[0],x[1],x[2],x[3],x[4]}`

Next we calculate a vector whose elements are all the same. We also calculate the unit vectors in a three-dimensional space:

`ConstantArray[0,5]` `{0,0,0,0,0}`

`Table[UnitVector[3,k],{k,3}]` `{{1,0,0},{0,1,0},{0,0,1}}`

3. Arithmetic of vectors. The arithmetic operations of multiplying a vector with a scalar and adding two vectors work in *Mathematica* as expected. However, note that *Mathematica* also does other types of arithmetic operations with vectors: multiplication, division, and powers. All arithmetic operations are done in an element-by-element way. For example, **`u v`** and **`u/v`** form a vector from the products or quotients of the corresponding elements of **`u`** and **`v`**. This is a useful property in many calculations, but remember to use **`u.v`** (which is the same as **`Dot[u, v]`**) for an inner product.

`u={a,b,c}; v={4,2,3};`

`{10v,u+v,u v}` `{{40,20,30},{4+a,2+b,3+c},{4a,2b,3c}}`

`{1/v,u/v,u^2}` $\{\{\frac{1}{4},\frac{1}{2},\frac{1}{3}\},\{\frac{a}{4},\frac{b}{2},\frac{c}{3}\},\{a^2,b^2,c^2\}\}$

Values of functions with vector arguments are also automatically calculated element-wise:

`Log[v]` `{Log[4],Log[2],Log[3]}`

4. Products of two vectors. With **`u`** and **`v`** as in Example 3, we calculate the inner product, the outer product, and the cross product:

`v.u` `4a+2b+3c`

`KroneckerProduct[v,u]` `{{4a,4b,4c},{2a,2b,2c},{3a,3b,3c}}`

`MatrixForm[%]` $\begin{pmatrix} \texttt{4a} & \texttt{4b} & \texttt{4c} \\ \texttt{2a} & \texttt{2b} & \texttt{2c} \\ \texttt{3a} & \texttt{3b} & \texttt{3c} \end{pmatrix}$

`Cross[v,u]` `{-3b+2c,3a-4c,-2a+4b}`

5. Sums and products of elements of vectors.

`Total[u]` `a+b+c`

`Apply[Times,u]` `a b c`

6. Norms of vectors. The default vector norm is the 2-norm:

`Norm[u]` $\sqrt{\texttt{Abs[a]}^2+\texttt{Abs[b]}^2+\texttt{Abs[c]}^2}$

`Norm[u,2]` $\sqrt{\texttt{Abs[a]}^2+\texttt{Abs[b]}^2+\texttt{Abs[c]}^2}$

`Norm[u,1]` `Abs[a]+Abs[b]+Abs[c]`

`Norm[u,∞]` `Max[Abs[a],Abs[b],Abs[c]]`

7. Distances between vectors.

`EuclideanDistance[{a,b},{x,y}]` $\sqrt{\texttt{Abs[a-x]}^2+\texttt{Abs[b-y]}^2}$

`ChessboardDistance[{a,b},{x,y}]` `Max[Abs[a-x],Abs[b-y]]`

`ManhattanDistance[{a,b},{x,y}]` `Abs[a-x]+Abs[b-y]`

`HammingDistance[{0,1,1,0,0},{0,0,1,1,1}]` `3`

8. Orthogonalization of vectors, etc.

`g = Orthogonalize[{{4,3},{2,7}}]` $\{\{\frac{4}{5},\frac{3}{5}\},\{-\frac{3}{5},\frac{4}{5}\}\}$

`g[[1]].g[[1]]` `1`

`g[[1]].g[[2]]` `0`

9. Taking a part of a vector.

`v={a,b,c,d,e,f};`

`v[[4]]` `d`

`v[[{1,3,5}]]` `{a,c,e}`

`v[[2;;4]]` `{b,c,d}`

```
v[[;;2]]      {a,b}
```

```
v[[2;;]]     {b,c,d,e,f}
```

```
v[[;;-2]]      {a,b,c,d,e}
```

```
v[[-2;;]]     {e,f}
```

10. Adding elements into vectors. Note that the following does not change the value of **v**:

```
Append[v,100]      {a,b,c,d,e,f,100}
```

```
v      {a,b,c,d,e,f}
```

In contrast, the following does change the value of **v**:

```
AppendTo[v,100]      {a,b,c,d,e,f,100}
```

```
v      {a,b,c,d,e,f,100}
```

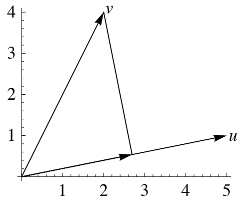
Applications

1. (Plotting of vectors) The graphics primitive **Arrow** can be used to plot vectors. As an example, we compute the orthogonal projection of a vector onto another vector and show the three vectors (for graphics primitives like **Arrow**, **Line**, and **Text**, see [Rus09, pp. 151–178]):

```
u={5,1}; v={2,4};
```

`pr=Projection[v,u]` $\left\{\frac{35}{13},\frac{7}{13}\right\}$

```
Graphics[{Arrowheads[Small],Arrow[{{0,0},u}],Arrow[{{0,0},v}],
  Arrow[{{0,0},pr}],
  Line[{v,pr}],Text["u",u,{-1.5,0}],Text["v",v,{-1.5,-0.5}]},
  Axes → True,ImageSize → 120]
```



90.3 Basics of Matrices

Commands

Matrices in *Mathematica* are lists of lists, each sublist being a row of the matrix. Although the traditional symbols for matrices are capital letters like A or M, we use the lower-case letter `m` for most matrices because, in *Mathematica*, all user-defined names should begin with a lower-case letter.

1. Matrices in *Mathematica*:

   - `m = {{a, b, ... }, {c, d, ... }, ... }` A matrix `m` with rows (`a`, `b`, ...), (`c`, `d`, ...), ...
   - `MatrixForm[m]` Display matrix `m` in a two-dimensional form.
   - `Length[m]` The number of rows of matrix `m`.
   - `Dimensions[m]` The number of rows and columns of matrix `m`.
   - The menu command *Insert* ▷ *Table/Matrix*: generate an empty matrix with slots for elements.

2. Generation of matrices:

   - `Table[expr, {i, m₁}, {j, n₁}]` Create a matrix by giving, in `expr`, `i` the values 1, 2, ..., m_1 and, for each `i`, `j` the values 1, ..., n_1. Other forms of an iteration specification are `{m₁}`, `{i, m₀, m₁}`, and `{i, m₀, m₁, d}` (see Command 90.2.2).
   - `Array[f, {m₁,n₁}]` Create an $m_1 \times n_1$ matrix with elements `f[i, j]`.
   - `Array[f, {m₁,n₁}, {m₀,n₀}]` Create an $m_1 \times n_1$ matrix using starting values m_0 and n_0 for the indices (the default values of m_0 and n_0 are 1).

3. Special matrices:

   - `IdentityMatrix[n]` The `n`×`n` identity matrix.
   - `IdentityMatrix[{m, n}]` The `m`×`n` identity matrix.
   - `DiagonalMatrix[v]` A diagonal matrix with list `v` as the main diagonal.
   - `DiagonalMatrix[v, k]` A diagonal matrix with list `v` as the `k`th diagonal.
   - `ConstantArray[c, {m, n}]` An `m`×`n` matrix with `c` as each element.
   - `HilbertMatrix[n]`, `HankelMatrix[n]`, `ToeplitzMatrix[n]`, `PauliMatrix[k]`.
   - `BoxMatrix[r]`, `CrossMatrix[r]`, `DiamondMatrix[r]`, `DiskMatrix[r]`, `GaussianMatrix[r]`.

4. Plots of matrices:

   - `MatrixPlot[m]` Plot a matrix by showing zero values as white squares, the maximum negative value as blue squares, the maximum positive value as orange squares, and other values as lighter blue and orange squares.
   - `MatrixPlot[m, ColorFunction → "Monochrome"]` Show all nonzero elements as black and zero elements as white.
   - `MatrixPlot[m, ColorRules → {rules}]` Color the elements according to the given rules.
   - `ArrayPlot[m]` Plot a matrix by showing zero values as white squares, the maximum absolute value as black squares, and values between as gray squares.

5. Sparse matrices:

   - `SparseArray[rules]` Create a sparse vector or matrix by taking non-zero elements from `rules` and setting other elements to zero. For vectors, `rules` is of the form $\{i_1 \to a_1, i_2 \to a_2, \ldots\}$ or $\{i_1, i_2, \ldots\} \to \{a_1, a_2, \ldots\}$ so that in position i_j we have the value a_j. For matrices, **`rules`** is of the form $\{\{i_1, j_1\} \to a_1, \{i_2, j_2\} \to a_2, \ldots\}$ or $\{\{i_1, j_1\}, \{i_2, j_2\}, \ldots\} \to \{a_1, a_2, \ldots\}$ so that in position $\{i_k, j_k\}$ we have the value a_k. The rules can contain patterns.

- **`SparseArray[rules, dims]`** Create a sparse vector or matrix of the size specified by **`dims`**. For vectors, **`dims`** is of the form {**`n`**} and for matrices of the form {**`m, n`**}.
- **`Normal[s]`** Show a sparse vector or matrix **`s`** in the usual list form.
- **`ArrayRules[m]`** Show all non-zero elements of a vector or matrix as rules.

6. Banded matrices:

- **`SparseArray[Band[`**$\{i, j\}$**`]`** $\to$ **`a]`** Create a sparse matrix where the diagonal that starts at (**`i`**, **`j`**) has all its elements equal to **`a`**.
- **`SparseArray[Band[`**$\{i, j\}$**`]`** $\to \{a_1, a_2, \ldots\}$**`]`** The diagonal that starts at (**`i`**, **`j`**) is the given vector.
- **`SparseArray[Band[`**$\{i, j\}$**`]`** $\to \{m_1, m_2, \ldots\}$**`]`** The diagonal that starts at (**`i`**, **`j`**) contains the given sequence of matrices.
- **`SparseArray[`**$\{$**`Band[`**$\{i_1, j_1\}$**`]`** $\to a_1$, **`Band[`**$\{i_2, j_2\}$**`]`** $\to a_2, \ldots\}$**`]`** Define several bands.
- **`Band[`**$\{i_1, j_1\}, \{i_2, j_2\}$**`]`** The band ends at position (i_2, j_2).
- **`Band[`**$\{i_1, j_1\}, \{i_2, j_2\}, \{d_1, d_2\}$**`]`** The band is defined by steps (d_1, d_2).

Examples

1. Matrices in *Mathematica*. Matrices are lists of rows:

`m={{5,2,3},{4,0,2}}` `{{5,2,3},{4,0,2}}`

`MatrixForm[m]`

$$\begin{pmatrix} 5 & 2 & 3 \\ 4 & 0 & 2 \end{pmatrix}$$

The number of rows and the size of the matrix are

`Length[m]` `2`

`Dimensions[m]` `{2,3}`

With the menu command *Insert* ▷ *Table/Matrix* we get a matrix with empty slots that can then be filled with the help of the Tab key:

$$\begin{pmatrix} \square & \square & \square \\ \square & \square & \square \end{pmatrix}$$

With the **`TableSpacing`** option of **`MatrixForm`** we can control the space between rows and columns (the default space is 1 for both rows and columns):

`MatrixForm[m,TableSpacing` $\to$ **`{.5,1}]`**

$$\begin{pmatrix} 5 & 2 & 3 \\ 4 & 0 & 2 \end{pmatrix}$$

Note that *Mathematica* will not do any calculations with a matrix that is in a matrix form! For example, writing

```
m={{5,2,3},{4,0,2}}//MatrixForm
```

$$\begin{pmatrix} 5 & 2 & 3 \\ 4 & 0 & 2 \end{pmatrix}$$

defines **(m** to be the matrix form of the given matrix and *Mathematica* does not do any calculations with this **m**. Write instead `MatrixForm[m = {{5, 2, 3}, {4, 0, 2}}]` or `(m = {{5, 2, 3}, {4, 0, 2}}) // MatrixForm` or do as we did above: first define the matrix with `m = {{5, 2, 3}, {4, 0, 2}}` and then display the matrix with `MatrixForm[m]`.

2. Generation of matrices.

```
Table[1/(i+j-1),{i,3},{j,3}]
```

$$\left\{\left\{1,\frac{1}{2},\frac{1}{3}\right\},\left\{\frac{1}{2},\frac{1}{3},\frac{1}{4}\right\},\left\{\frac{1}{3},\frac{1}{4},\frac{1}{5}\right\}\right\}$$

If, **Which**, and **Switch** are often useful in connection with **Table**. In the following examples, we form the same tridiagonal matrix in three ways (we show the result only for the first example):

```
Table[If[i==j,13,If[i==j-1,11,If[i==j+1,12,0]]],{i,4},{j,4}]

//MatrixForm
```

$$\begin{pmatrix} 13 & 11 & 0 & 0 \\ 12 & 13 & 11 & 0 \\ 0 & 12 & 13 & 11 \\ 0 & 0 & 12 & 13 \end{pmatrix}$$

```
Table[Which[i==j,13,i==j-1,11,i==j+1,12,True,0],{i,4},{j,4}];

Table[Switch[i-j,-1,11,0,13,1,12,_,0],{i,4},{j,4}];
```

Here is a matrix with general elements:

```
Array[f,{2,2}]        {{f[1,1],f[1,2]},{f[2,1],f[2,2]}}
```

3. Special matrices.

```
IdentityMatrix[3]        {{1,0,0},{0,1,0},{0,0,1}}

DiagonalMatrix[{3,1,2}]        {{3,0,0},{0,1,0},{0,0,2}}
```

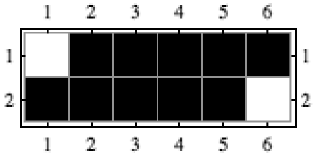
`HilbertMatrix[3]` $\left\{\left\{1,\frac{1}{2},\frac{1}{3}\right\},\left\{\frac{1}{2},\frac{1}{3},\frac{1}{4}\right\},\left\{\frac{1}{3},\frac{1}{4},\frac{1}{5}\right\}\right\}$

4. Plots of matrices.

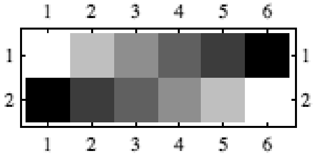
```
(m={Range[0,5],Range[-5,0]})//MatrixForm
```

$$\begin{pmatrix} 0 & 1 & 2 & 3 & 4 & 5 \\ -5 & -4 & -3 & -2 & -1 & 0 \end{pmatrix}$$

```
MatrixPlot[m,ColorFunction → "Monochrome",Mesh → True,
  ImageSize → 160]
```



```
ArrayPlot[m,FrameTicks → Automatic,ImageSize → 160]
```



5. Sparse matrices. We generate a sparse matrix in two ways:

```
m=SparseArray[{{1,1} → 3,{2,3} → 2,{3,2} → 4}]

SparseArray[<3>,{3,3}]

m=SparseArray[{{1,1},{2,3},{3,2}} → {3,2,4}]

SparseArray[<3>,{3,3}]
```

Here is this matrix in the usual list form:

```
Normal[m]       {{3,0,0},{0,0,2},{0,4,0}}
```

With sparse matrices, we can calculate in the same way as with usual matrices:

```
2 m

SparseArray[<3>,{3,3}]

Transpose[m]

SparseArray[<3>,{3,3}]
```

Next, we generate the same tridiagonal matrix as we generated in Example 2 with `Table`. Now we use patterns:

```
m=SparseArray[{{i_,i_} → 13,  {i_,j_}/;i-j==-1 → 11, {i_,j_}/;
i-j==1 → 12},{4,4}]

SparseArray[<10>,{4,4}]

m//MatrixForm
```

$$\begin{pmatrix} 13 & 11 & 0 & 0 \\ 12 & 13 & 11 & 0 \\ 0 & 12 & 13 & 11 \\ 0 & 0 & 12 & 13 \end{pmatrix}$$

Here are all the rules of this sparse matrix:

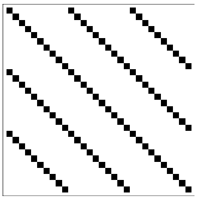
```
ArrayRules[m]
```

```
{{1,2} → 11,{1,1} → 13,{2,1} → 12,{2,2} → 13,{2,3} → 11,{3,4} → 11,
{3,2} → 12,{3,3} → 13,{4,3} → 12,{4,4} → 13,{_,_} → 0}
```

Here is a larger sparse matrix:

```
m=SparseArray[{i_,j_}/;Mod[i-j,10]==0 → 1,{30,30}];

ArrayPlot[m,ImageSize → 100]
```



6. Banded matrices. Create some banded matrices:

```
SparseArray[Band[{1,1}] → 5,{3,3}]
```

```
SparseArray[<3>,{3,3}]
```

```
Normal[%]      {{5,0,0},{0,5,0},{0,0,5}}
```

```
SparseArray[Band[{1,1}] → {3,4,5},{3,3}]//Normal
```

```
{{3,0,0},{0,4,0},{0,0,5}}
```

Create a tridiagonal matrix:

```
SparseArray[{Band[{1,1}] → a,Band[{2,1}] → b,Band[{1,2}] → c},{4,4}]
//MatrixForm
```

$$\begin{pmatrix} a & c & 0 & 0 \\ b & a & c & 0 \\ 0 & b & a & c \\ 0 & 0 & b & a \end{pmatrix}$$

Create a non-zero row:

```
SparseArray[Band[{2,1},{2,4},{0,1}] → 5,{4,4}]//MatrixForm
```

$$\begin{pmatrix} 0 & 0 & 0 & 0 \\ 5 & 5 & 5 & 5 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

90.4 Matrix Algebra

Commands

1. Transpose:
   - `Transpose[m]` or `m`$^{\mathsf{T}}$ Transpose; write $^{\mathsf{T}}$ as $\boxed{\text{ESC}}$tr$\boxed{\text{ESC}}$.
   - `ConjugateTranspose[m]` or `m`$^{\mathsf{H}}$ Conjugate transpose; write $^{\mathsf{H}}$ (Hermitian conjugate) as $\boxed{\text{ESC}}$hc$\boxed{\text{ESC}}$. `ConjugateTranspose[m]` is equivalent to `Conjugate[Transpose[m]]` or `(m`$^{\mathsf{T}}$`)`*; write * (conjugate) as $\boxed{\text{ESC}}$co$\boxed{\text{ESC}}$.
2. Tests:
   - `MatrixQ[m]` Test whether `m` is a matrix.
   - `SymmetricMatrixQ[m]` Test whether `m` is symmetric (`m` $=$ `m`$^{\mathsf{T}}$).
   - `HermitianMatrixQ[m]` Test whether `m` is a Hermitian matrix (`m` $=$ `m`†).
   - `PositiveDefiniteMatrixQ[m]` Test whether `m` is positive definite.
3. Sums and products of elements:
   - `Tr[m]` The trace (i.e., the sum of the elements on the leading diagonal).
   - `Tr[m, Times]` The product of the elements on the leading diagonal.
   - `Total[m]` The vector of column sums (i.e., the sum of the rows).
   - `Total[m`$^{\mathsf{T}}$`]` The vector of row sums (i.e., the sum of the columns).
   - `Total[Flatten[m]]` The sum of all elements.
4. Arithmetic:
   - `a m` Multiply matrix `m` by scalar `a`.
   - `m + n` Add two matrices.
   - `m n` Multiply *the corresponding elements* of two matrices (giving the Hadamard product of the matrices; there is a space between `m` and `n`); for a proper matrix product, write `m.n` (see item 5).
   - `m^p` Calculate the `p`th power of *each element* of a matrix; for a proper matrix power, write `MatrixPower[m, p]` (see item 6).
   - `m^-1` Calculate the reciprocal of *each element* of a matrix; for a proper matrix inverse, write `Inverse[m]` (see item 8).
5. Products:
   - `m.n` Product of two matrices.
   - `m.v` Product of a matrix and a (column) vector.
   - `v.m` Product of a (row) vector and a matrix.

- **`KroneckerProduct[m, n]`** The Kronecker product of the two matrices.

6. Matrix power and matrix exponential:

- **`MatrixPower[m, p]`** The **`p`**th matrix power of a square matrix.
- **`MatrixPower[m, p, v]`** The matrix power applied to a vector.
- **`MatrixExp[m]`** The matrix exponential $e^{\mathtt{m}} = \sum_{i=0}^{\infty} \frac{1}{i!}\mathtt{m}^i$ of a square matrix.
- **`MatrixExp[m, v]`** The matrix exponential applied to a vector.

7. Determinant and minors:

- **`Det[m]`** Determinant of a square matrix.
- **`Minors[m]`** Minors of a square matrix.
- **`Minors[m, k]`** **`k`**th minors.

8. Inverse and pseudo-inverse:

- **`Inverse[m]`** Inverse of a square matrix.
- **`PseudoInverse[m]`** Pseudo-inverse (of a possibly rectangular matrix).

9. Norms:

- **`Norm[m]`** or **`Norm[m, 2]`** The 2-norm (the maximum of the singular values).
- **`Norm[m, 1]`** The 1-norm (the maximum of the absolute column sums).
- **`Norm[m, ∞]`** The ∞-norm (the maximum of the absolute row sums)
- **`Norm[m, "Frobenius"]`** The Frobenius norm (the square root of the sum of squares of absolute values).

10. Null space, rank, and row reduction:

- **`NullSpace[m]`** Basis vectors of the null space (kernel).
- **`MatrixRank[m]`** Rank (i.e., the number of linearly independent rows or columns).
- **`RowReduce[m]`** Do Gauss-Jordan elimination to produce the reduced row echelon form.

Examples

1. Transpose.

```
m={{2+3I,1-2I},{3-4I,4+I}};
```

`MatrixForm[m]` $\begin{pmatrix} 2+3i & 1-2i \\ 3-4i & 4+i \end{pmatrix}$

`MatrixForm[m`$^{\mathsf{T}}$`]` $\begin{pmatrix} 2+3i & 3-4i \\ 1-2i & 4+i \end{pmatrix}$

`MatrixForm[m`†`]` $\begin{pmatrix} 2-3i & 3+4i \\ 1+2i & 4-i \end{pmatrix}$

2. Tests. A Hermitian matrix is positive definite if and only if all eigenvalues are positive:

```
(m={{2,3+I},{3-I,7}})//MatrixForm
```

$$\begin{pmatrix} 2 & 3+i \\ 3-i & 7 \end{pmatrix}$$

```
HermitianMatrixQ[m]     True

PositiveDefiniteMatrixQ[m]     True

N[Eigenvalues[m]]     {8.53113,0.468871}
```

If `m` is positive definite, it means that `x.m.x` is positive for all nonzero vectors `x`:

```
Reduce[Simplify[{x,y}.m.{x,y}]>0,Reals]

y<0||(y==0&&(x<0||x>0))||y>0
```

3. Sums and products of elements.

```
(m={{a,b,c},{d,e,f},{g,h,i}})//MatrixForm
```

$$\begin{pmatrix} a & b & c \\ d & e & f \\ g & h & i \end{pmatrix}$$

```
Tr[m]     a+e+i

Tr[m,Times]     a e i

Total[m]     {a+d+g,b+e+h,c+f+i}
```

$\texttt{Total[m}^{\texttt{T}}\texttt{]} \qquad \{\texttt{a+b+c,d+e+f,g+h+i}\}$

```
Total[Flatten[m]]     a+b+c+d+e+f+g+h+i
```

4. Arithmetic.

```
Map[MatrixForm,{m={{2,3},{4,5}},n={{a,b},{c,d}}}]
```

$$\left\{\begin{pmatrix} 2 & 3 \\ 4 & 5 \end{pmatrix}, \begin{pmatrix} a & b \\ c & d \end{pmatrix}\right\}$$

```
Map[MatrixForm,{2 n, m+n, m n, m^2, m^-1}]
```

$$\left\{\begin{pmatrix} 2a & 2b \\ 2c & 2d \end{pmatrix}, \begin{pmatrix} 2+a & 3+b \\ 4+c & 5+d \end{pmatrix}, \begin{pmatrix} 2a & 3b \\ 4c & 5d \end{pmatrix}, \begin{pmatrix} 4 & 9 \\ 16 & 25 \end{pmatrix}, \begin{pmatrix} \frac{1}{2} & \frac{1}{3} \\ \frac{1}{4} & \frac{1}{5} \end{pmatrix}\right\}$$

5. Products. Consider the following matrices and vectors:

```
m={{1,2,3},{4,5,6}};
n={{p,q},{r,s},{t,u}};
```

```
v={1,2};

w={1,2,3};

Map[MatrixForm,{m,n,v,w}]
```

$$\left\{\begin{pmatrix}1 & 2 & 3\\ 4 & 5 & 6\end{pmatrix},\begin{pmatrix}p & q\\ r & s\\ t & u\end{pmatrix},\begin{pmatrix}1\\ 2\end{pmatrix},\begin{pmatrix}1\\ 2\\ 3\end{pmatrix}\right\}$$

Here are some products:

```
Map[MatrixForm,{m.n,n.v,w.n}]
```

$$\left\{\begin{pmatrix}p+2r+3t & q+2s+3u\\ 4p+5r+6t & 4q+5s+6u\end{pmatrix},\begin{pmatrix}p+2q\\ r+2s\\ t+2u\end{pmatrix},\begin{pmatrix}p+2r+3t\\ q+2s+3u\end{pmatrix}\right\}$$

```
KroneckerProduct[m,n]//MatrixForm
```

$$\begin{pmatrix}p & q & 2p & 2q & 3p & 3q\\ r & s & 2r & 2s & 3r & 3s\\ t & u & 2t & 2u & 3t & 3u\\ 4p & 4q & 5p & 5q & 6p & 6q\\ 4r & 4s & 5r & 5s & 6r & 6s\\ 4t & 4u & 5t & 5u & 6t & 6u\end{pmatrix}$$

6. Matrix power and matrix exponential. Powers can be calculated with **`MatrixPower`** or by using the dot repeatedly:

```
k={{2,3},{-2,1}};

MatrixPower[k,4]      {{-50,-63},{42,-29}}

k.k.k.k      {{-50,-63},{42,-29}}

MatrixExp[k//N]      {{-2.6658,3.79592},{-2.53061,-3.93111}}
```

7. Determinant and minors. First we consider a nonsingular matrix:

```
m={{6,2,3},{2,7,5},{4,2,5}};

Det[m]      98

Minors[m]      {{38,24,-11},{4,18,4},{-24,-10,25}}
```

Here is a singular matrix:

```
n={{7,7,2,7},{2,5,0,7},{8,7,8,3},{5,6,4,5}};
```

```
Det[n]       0
```

8. Inverse and pseudo-inverse. First we consider the nonsingular matrix **m** from Example 4:

```
i=Inverse[m]
```

$$\left\{\left\{\frac{25}{98}, -\frac{2}{49}, -\frac{11}{98}\right\}, \left\{\frac{5}{49}, \frac{9}{49}, -\frac{12}{49}\right\}, \left\{-\frac{12}{49}, -\frac{2}{49}, \frac{19}{49}\right\}\right\}$$

```
m.i==IdentityMatrix[3]      True
```

Then we consider the singular matrix **n**. The inverse does not exist, but the Moore−Penrose pseudo-inverse does exist:

```
Inverse[n]
```

```
Inverse[{{7,7,2,7},{2,5,0,7},{8,7,8,3},{5,6,4,5}}]
```

```
ps=PseudoInverse[n]
```

$$\left\{\left\{\frac{1425}{4391}, -\frac{18625}{79038}, -\frac{1867}{79038}, -\frac{5123}{39519}\right\}, \left\{-\frac{241}{4391}, \frac{923}{13173}, \frac{275}{13173}, \frac{599}{13173}\right\}, \left\{-\frac{1126}{4391}, \frac{4046}{39519}, \frac{4802}{39519}, \frac{4424}{39519}\right\}, \left\{-\frac{235}{4391}, \frac{10775}{79038}, -\frac{2527}{79038}, \frac{2062}{39519}\right\}\right\}$$

We check the four characterizing properties of a pseudo-inverse:

```
{n.ps.n==n, ps.n.ps==ps, (n.ps)†==n.ps, (ps.n)†==ps.n}
```

```
{True,True,True,True}
```

For the option **`Tolerance`** of **`PseudoInverse`**, see **`SingularValueList`** in Section 90.7.

9. Norms.

```
m={{3,1},{4,2}};
```

```
{Norm[m,1], Norm[m,2], Norm[m,∞], Norm[m,"Frobenius"]}
```

$$\left\{7, \sqrt{15+\sqrt{221}}, 6, \sqrt{30}\right\}$$

Norms are easy to program:

```
{Max[Total[Abs[m]]],First[SingularValueList[m]],Max[Total[Abs[m^T]]],
Sqrt[Total[Flatten[Abs[m]^2]]]}
```

$$\left\{7, \sqrt{15+\sqrt{221}}, 6, \sqrt{30}\right\}$$

10. Null space, rank, and row reduction. The null space (or kernel) of a matrix M consists of vectors v for which $Mv = 0$. **`NullSpace`** gives a list of basis vectors for the null space. The matrix multiplied with any linear combination of these basis vectors gives a zero vector. For a nonsingular matrix M, the null space is empty (*Mathematica* gives the empty list {}); that is, there is no nonzero vector v such that $Mv = 0$. The null space of the following matrix contains two basis vectors:

```
p={{7,4,8,0},{7,4,8,0},{1,8,3,3}};
```

```
ns=NullSpace[p]        {{12,-21,0,52},{-4,-1,4,0}}
```

The matrix **`p`** multiplied with any linear combination of the basis vectors gives a null vector:

```
Simplify[p.(a ns[[1]]+b ns[[2]])]        {0,0,0}
```

Matrix **`p`** is rank deficient:

```
MatrixRank[p]       2
```

The number of basis vectors of the null space plus the rank is the number of columns:

```
Length[NullSpace[p]]+MatrixRank[p]       4
```

The reduced row echelon form of a nonsingular square matrix is the identity matrix. Here is the reduced row echelon form of **`p`**:

```
RowReduce[p]//MatrixForm
```

$$\begin{pmatrix} 1 & 0 & 1 & -\frac{3}{13} \\ 0 & 1 & \frac{1}{4} & \frac{21}{52} \\ 0 & 0 & 0 & 0 \end{pmatrix}$$

The number of nonzero rows in the reduced row echelon form is the rank. **`RowReduce`** is also considered in Command 90.9.4.

Applications

1. (Determinant) We know that the determinant of the (1×1) matrix $\{\{m\}\}$ is m and the determinant of an $(n \times n)$ matrix m is $\sum_{j=1}^{n}(-1)^{j+1}m_{1j}c_j$, where c_j is the determinant of the matrix that is obtained from m by deleting the first row and the jth column. Thus, we arrive at the following recursive definition:

```
det[{{m_}}]:=m

det[m_]:=det[m]=Sum[(-1)^(j+1)m[[1,j]]det[Drop[m,{1},{j}]],

  {j,Length[m]}]
```

Here, note the use of the so-called dynamic programming: `det[m_] := det[m] = Sum`.... This has the effect that all calculated determinants are saved into memory. If we would write `det[m_] := Sum`..., we would get a much slower program. Let us try this recursive function to a random matrix:

```
m=RandomReal[{0,1},{6,6}];
```

```
{det[m],Det[m]}       {-0.102166,-0.102166}
```

2. (Permanent) See Chapter 43 for the definition and more information about permanents. A permanent of a square matrix M with n rows can be computed as the coefficient of the product $x_1 x_2 \cdots x_n$ in the product of the components of the vector Mv, where $v = (x_1, \ldots, x_n)$. So, a permanent can be calculated with the following program:

```
permanent[m_]:=With[{v=Array[x,Length[m]]},

  Coefficient[Apply[Times,m.v],Apply[Times,v]]]

m={{6,2,3},{2,7,5},{4,2,5}};

permanent[m]      426
```

3. (Solving linear differential equations) Solve a system of linear differential equations:

```
eqns={x'[t]==y[t],y'[t]==x[t]+z[t],z'[t]==z[t],x[0]==1,y[0]==0,

z[0]==1}

{x'[t]==y[t],y'[t]==x[t]+z[t],z'[t]==z[t],x[0]==1,y[0]==0,z[0]==1}

DSolve[eqns,{x[t],y[t],z[t]},t]//Simplify
```

$$\left\{\left\{\mathtt{x[t]} \to \tfrac{1}{4}e^{-t}(3+e^{2\,t}(1+2t)),\mathtt{y[t]} \to \tfrac{1}{4}e^{-t}(-3+e^{2\,t}(3+2t)),\mathtt{z[t]} \to e^{t}\right\}\right\}$$

The solution can also be computed by using the matrix exponential applied to the vector of initial conditions:

```
MatrixExp[{{0,1,0},{1,0,1},{0,0,1}} t,{1,0,1}]//Simplify
```

$$\left\{\tfrac{1}{4}e^{-t}(3+e^{2\,t}(1+2t)),\tfrac{1}{4}e^{-t}(-3+e^{2\,t}(3+2t)),e^{t}\right\}$$

90.5 Manipulation of Matrices

Commands

1. Taking and resetting elements:

- **`m[[i, j]]`** Take element (**`i`**, **`j`**) (output is the corresponding scalar).
- **`m[[i, j]] = a`** Change the value of element (**`i`**, **`j`**) into scalar **`a`** (output is **`a`**).

2. Taking, dropping, and inserting rows (the output is the corresponding vector or matrix):

- **`m[[i]]`** Take row **`i`**.
- **`m[[i ;; j]]`** Take rows **`i`** through **`j`**.
- **`m[[{i, j, ... }]]`** Take the given rows.
- **`First[m]`**, **`Last[m]`** Take the first/last row.
- **`Rest[m]`**, **`Most[m]`** Drop the first/last row.
- **`Take[m, n]`**, **`Take[m, -n]`**, **`Take[m, {n₁, n₂}]`** Take the first **`n`** rows/the last **`n`** rows/rows `n₁`, ..., `n₂`.
- **`Drop[m, n]`**, **`Drop[m, -n]`**, **`Drop[m, {n₁, n₂}]`** Drop the first **`n`** rows/the last **`n`** rows/rows `n₁`, ..., `n₂`.
- **`Prepend[m, r]`**, **`Append[m, r]`** Insert row **`r`** at the beginning/end of a matrix.

- **Insert[m, r, i]** Insert row **r** between rows **i-1** and **i**(so, **r** becomes row **i**).
- **Delete[m, i]** Delete the **i**th row.

3. Taking, dropping, and inserting columns (output is the corresponding vector or matrix):
   - **m[[All, j]]** or **m**$^{\mathsf{T}}$**[[j]]** Take column **j**.
   - **m[[All, i ;; j]]** Take columns **i** through **j**.
   - **m[[All, {i, j, ... }]]** Take the given columns.
   - **Take[m, All, n]**, **Drop[m, None, n]** Take/drop the first **n** columns.
   - **Prepend[m**$^{\mathsf{T}}$**, c]**$^{\mathsf{T}}$, **Append[m**$^{\mathsf{T}}$**, c]**$^{\mathsf{T}}$ Insert column **c** at the left/right of **m**.
   - **Drop[m, {}, {j}]** Delete the **j**th column.
   - **Drop[m, {i}, {j}]** Delete the **i**th row and the **j**th column.

4. Taking diagonals:
   - **Diagonal[m]** List of elements on the leading diagonal.
   - **Diagonal[m, k]** List of elements on the **k**th diagonal.

5. Taking submatrices:
   - **m[[{**$\mathtt{i_1}$**,** $\mathtt{i_2}$**, ... }, {**$\mathtt{j_1}$**,** $\mathtt{j_2}$**, ... }]** Take the elements having the given indices.
   - **m[[**$\mathtt{i_1}$ **;;** $\mathtt{i_2}$**,** $\mathtt{j_1}$ **;;** $\mathtt{j_2}$**]]** or **Take[m,{**$\mathtt{i_1}$**,** $\mathtt{i_2}$**}, {**$\mathtt{j_1}$**,** $\mathtt{j_2}$**}]** Take the elements having row indices between $\mathtt{i_1}$ and $\mathtt{i_2}$ and column indices between $\mathtt{j_1}$ and $\mathtt{j_2}$.

6. Combining and extending matrices:
   - **ArrayFlatten[{{m},{n}}]** or **Join[m, n]** Put matrices one below the other.
   - **ArrayFlatten[{{m, n}}]** or **Join[m, n, 2]** or **Join[m**$^{\mathsf{T}}$**, n**$^{\mathsf{T}}$**]**$^{\mathsf{T}}$ Put matrices side by side.
   - **ArrayFlatten[{{m, n}, {p, q}}]** Combine the matrix of matrices into one matrix.
   - **PadRight[m, {**$\mathtt{n_1}$**,** $\mathtt{n_2}$**}]** Extend **m** with zeros to an $\mathtt{n_1} \times \mathtt{n_2}$ matrix.
   - **PadRight[m, {**$\mathtt{n_1}$**,** $\mathtt{n_2}$**}, a]** Extend **m** with replicates of matrix **a** to an $\mathtt{n_1} \times \mathtt{n_2}$ matrix.

7. Permuting rows and columns:
   - **Transpose[m]** or **m**$^{\mathsf{T}}$ Interchange rows and columns.
   - **m[[{**$\mathtt{i_1}$**, ...,**$\mathtt{i_n}$**}]]**, **m**$^{\mathsf{T}}$**[[{**$\mathtt{j_1}$**, ...,**$\mathtt{j_n}$**}]]**$^{\mathsf{T}}$ Permute the rows/columns into the given order.
   - **RotateLeft[m]**, **RotateLeft[m**$^{\mathsf{T}}$**]**$^{\mathsf{T}}$, Move the first row/column to be the last row/column.
   - **RotateRight[m]**, **RotateRight[m**$^{\mathsf{T}}$**]**$^{\mathsf{T}}$ Move the last row/column to be the first row/column.
   - **Reverse[m]**, **Reverse[m**$^{\mathsf{T}}$**]**$^{\mathsf{T}}$ Reverse the order of the rows/columns.

8. Flattening and partitioning:
   - **Flatten[m]** Flatten out a matrix into a vector by concatenating the rows.
   - **Partition[v, k]** Partition a vector into a matrix having **k** columns and as many rows as become complete.
   - **Partition[m, {i, j}]** Partition **m** into blocks of size (**i**×**j**).

9. Triangularizing:
   - **LowerTriangularize[m]** Replace all but the lower triangular elements with zeros.
   - **LowerTriangularize[m, k]** Replace with zeros only the elements above the **k**th subdiagonal.

- **`UpperTriangularize[m]`** Replace all but the upper triangular elements with zeros.
- **`UpperTriangularize[m, k]`** Replace with zeros only the elements below the **`k`**th subdiagonal.

Examples

6. Combining and extending matrices. Consider the following matrices:

```
m={{a,b},{c,d}}; n={{e},{f}};
p={{g,h}}; q={{i}};
```

```
Map[MatrixForm,{m,n,p,q}]
```

$$\left\{\begin{pmatrix} a & b \\ c & d \end{pmatrix}, \begin{pmatrix} e \\ f \end{pmatrix}, \begin{pmatrix} g & h \end{pmatrix}, \begin{pmatrix} i \end{pmatrix}\right\}$$

Put matrices **`m`** and **`p`** one below the other:

```
Map[MatrixForm,{ArrayFlatten[{{m},{p}}],Join[m,p]}]
```

$$\left\{\begin{pmatrix} a & b \\ c & d \\ g & h \end{pmatrix}, \begin{pmatrix} a & b \\ c & d \\ g & h \end{pmatrix}\right\}$$

Put matrices **`m`** and **`n`** side by side:

```
Map[MatrixForm,{ArrayFlatten[{{m,n}}], Join[m,n,2], Join[mᵀ,nᵀ]ᵀ}]
```

$$\left\{\begin{pmatrix} a & b & e \\ c & d & f \end{pmatrix}, \begin{pmatrix} a & b & e \\ c & d & f \end{pmatrix}, \begin{pmatrix} a & b & e \\ c & d & f \end{pmatrix}\right\}$$

Combine the matrix {{**`m`**, **`n`**}, {**`p`**, **`q`**}} of matrices into one matrix:

```
ArrayFlatten[{{m,n},{p,q}}]//MatrixForm
```

$$\begin{pmatrix} a & b & e \\ c & d & f \\ g & h & i \end{pmatrix}$$

90.6 Eigenvalues

Commands

1. Eigenvalues and eigenvectors:

- **`CharacteristicPolynomial[m, x]`** Characteristic polynomial of a square matrix [note that *Mathematica* defines the characteristic polynomial of a matrix M to be $\det(M - xI)$ while the handbook uses the definition $\det(xI - M)$].

- **`Eigenvalues[m]`** Eigenvalues of a square matrix, in order of decreasing absolute value (repeated eigenvalues appear with their appropriate multiplicity). (The eigenvalues of **`m`** are those λ for which **`m.v=`**λ**`v`** for some non-zero eigenvector **`v`**.)
- **`Eigenvectors[m]`** Eigenvectors of a square matrix, in order of decreasing absolute value of their eigenvalues (eigenvectors are not normalized).
- **`Eigensystem[m]`** Eigenvalues and eigenvectors of a square matrix.

2. Options:

- **`Eigenvalues`**, **`Eigenvectors`**, and **`Eigensystem`** have the options **`Cubics`** and **`Quartics`** with default value **`False`**; if you want explicit radicals for all cubics and quartics, set **`Cubics`** → **`True`** and **`Quartics`** → **`True`**.

3. Largest eigenvalues and generalized eigenvalues:

- **`Eigenvalues[m, k]`** Calculate the **`k`** largest eigenvalues; similarly for **`Eigenvectors`** and **`Eigensystem`**.
- **`Eigenvalues[{m, a}]`** Calculate the generalized eigenvalues of matrix **`m`** with respect to matrix **`a`**; similarly for **`Eigenvectors`** and **`Eigensystem`**. (The generalized eigenvalues of **`m`** with respect to **`a`** are those λ for which **`m.v =`** λ **`a.v`** for some non-zero vector **`v`**.)

Examples

1. Eigenvalues. First we calculate the characteristic polynomial of **`m`** in two ways:

```
m={{6,2,3},{2,7,5},{4,2,5}};
```

`chp=CharacteristicPolynomial[m,x]` $98-81x+18x^2-x^3$

`Det[m-xIdentityMatrix[3]]` $98-81x+18x^2-x^3$

Then we calculate the eigenvalues in two ways:

`lam=Eigenvalues[m]` $\{8+\sqrt{15}, 8-\sqrt{15}, 2\}$

`Solve[chp==0]` $\{\{x \to 2\}, \{x \to 8-\sqrt{15}\}, \{x \to 8+\sqrt{15}\}\}$

Here are the eigenvectors:

`vec=Eigenvectors[m]`

$$\left\{\left\{1, -\frac{9}{2}+\frac{1}{2}\left(8+\sqrt{15}\right), 1\right\}, \left\{1, -\frac{9}{2}+\frac{1}{2}\left(8-\sqrt{15}\right), 1\right\}, \{-5, -14, 16\}\right\}$$

An eigenvalue λ of a matrix M and the corresponding eigenvector x should satisfy $Mx = \lambda x$. We check this for the first eigenvalue and then for all the eigenvalues:

`m.vec[[1]]==lam[[1]]vec[[1]]`   True

m.vec$^{\mathbf{T}}$==vec$^{\mathbf{T}}$.DiagonalMatrix[lam]   True

With **`Eigensystem`** we can compute both the eigenvalues and the eigenvectors. The result is a list where the first element is a list of eigenvalues and the second element is a list of the corresponding eigenvectors:

```
{lam,vec}=Eigensystem[m]
```

$$\left\{\left\{8+\sqrt{15},8-\sqrt{15},2\right\},\left\{\left\{1,-\tfrac{9}{2}+\tfrac{1}{2}\left(8+\sqrt{15}\right),1\right\},\right.\right.$$
$$\left.\left.\left\{1,-\tfrac{9}{2}+\tfrac{1}{2}\left(8-\sqrt{15}\right),1\right\},\{-5,-14,16\}\right\}\right\}$$

2. Options. For more complex eigenvalues we may get only representations of the values as some root objects, but with **`N`** we get numerical values:

```
n={{7,7,2,7},{2,5,0,7},{8,7,8,3},{5,6,4,5}};
```

```
Eigenvalues[n]
```

$$\left\{\text{Root}\left[-171+112\#1-25\#1^2+\#1^3\&,1\right],\text{Root}\left[-171+112\#1-25\#1^2\right.\right.$$
$$\left.\left.+\#1^3\&,3\right],\text{Root}\left[-171+112\#1-25\#1^2+\#1^3\&,2\right],0\right\}$$

```
N[%]      {19.7731,2.61345 +1.34834 i,2.61345 -1.34834 i,0.}
```

Often we only need the decimal values of the eigenvalues (not their exact expressions), and then we can input the matrix **`m//N`**:

```
Eigenvalues[n//N]
```

$$\{19.7731, 2.61345+1.34834\, i, 2.61345-1.34834\, i, -2.02041\times 10^{-15}\}$$

With the **`Cubics`** and **`Quartics`** options we may get explicit eigenvalues:

```
Eigenvalues[n,1,Cubics → True]//Simplify
```

$$\left\{\tfrac{1}{3}\left(25+\left(\tfrac{1}{2}\left(10667-261\sqrt{253}\right)\right)^{1/3}+\left(\tfrac{1}{2}\left(10667+261\sqrt{253}\right)\right)^{1/3}\right)\right\}$$

Applications

1. (A sufficient condition for a minimum or maximum) Consider the following function:

```
f=-3x+x^3 -y+2x y+x^2y^2
```
$-3x+x^3-y+2xy+x^2y^2$

It has a local point of minimum and we can calculate it with **`Minimize`**:

```
Minimize[{f,x>0.1,y<0},{x,y}]
```

```
{-2.2688,{x → 1.07442,y → -0.497601}}
```

We can also use classical optimization by first calculating the gradient:

```
grad=D[f,{{x,y},1}]
```
$\{-3+3x^2+2y+2xy^2,-1+2x+2x^2y\}$

Then we find the stationary points, that is, the points where the gradient is zero:

```
stat=NSolve[grad==0,{x,y}]
```

```
{{x → −1.16294,y → 1.22959},{x → −0.140442+0.584262i,y → −0.844491+
2.24741 i},{x → −0.140442−0.584262i,y → −0.844491−2.24741i},{x →
1.07442,y → −0.497601},{x → 0.369407,y → 0.956992}}
```

We pick the real points:

```
stat2=stat[[{1,4,5}]]
```

```
{{x → −1.16294,y → 1.22959},{x → 1.07442,y → −0.497601},
{x → 0.369407,y → 0.956992}}
```

A sufficient condition for a local minimum [maximum] point of a function is that the Hessian is positive [negative] definite. Thus, we then calculate the Hessian and its eigenvalues at the stationary points:

```
hes=D[f,{{x,y},2}]        {{6x + 2y^2,2 + 4xy},{2 + 4xy,2x^2}}
```

```
Map[Eigenvalues[hes/.#]&,stat2]
```

```
{{-5.61664,4.36764},{6.94587,2.30462},{6.06166,-1.74063}}
```

So, the Hessian is positive definite at the second point and indefinite at the first and third points. Thus, the second point is a minimum point and the first and third points are saddle points. For a program for classical optimization with constraints, see [Rus09, pp. 773–777].

2. (Eigenvector−eigenvalue decomposition) Let diag(λ) be a diagonal matrix whose diagonal elements are the eigenvalues of a matrix M, and let P be a matrix whose columns are the eigenvectors of M. If P is nonsingular, we have the decomposition $M = P\text{diag}(\lambda)P^{-1}$ or diagonalization $P^{-1}MP = \text{diag}(\lambda)$. The former equality shows that M and diag(λ) are similar matrices, so that, for example, they have the same determinant, trace, and rank. See Section 4.4 for more information about diagonalization. As an example of the eigenvector−eigenvalue decomposition, first compute the eigenvalues and eigenvectors:

```
m={{6,2,3},{2,7,5},{4,2,5}};
```

```
{lam,vec}=Eigensystem[m]
```

```
{{8 + √15,8 − √15,2},{{1, − 9/2 + 1/2 (8 + √15),1},{1, − 9/2 + 1/2 (8 − √15),1},
{−5, − 14,16}}}
```

Then define the diagonal matrix of eigenvalues and the matrix whose columns are the eigenvectors:

```
diag=DiagonalMatrix[lam]
```

```
{{8 + √15,0,0},{0,8 − √15,0},{0,0,2}}
```

```
p=vec^T
```

```
{{1,1, − 5},{− 9/2 + 1/2 (8 + √15), − 9/2 + 1/2 (8 − √15), − 14},{1,1,16}}
```

The following computation verifies the decomposition:

```
p.diag.Inverse[p]==m     True
```

90.7 Singular Values

Commands

1. Singular values:

- **`SingularValueList[m]`** Non-zero singular values of a (possibly rectangular) matrix; the singular values are given in order of decreasing value (repeated singular values appear with their appropriate multiplicity).

2. Singular value decomposition:

- **`SingularValueDecomposition[m]`** Singular value decomposition of a (possibly rectangular) matrix. For matrix M, the decomposition is $M = UWV^\dagger$ where U and V are orthonormal and W is diagonal with singular values as the diagonal elements († means conjugate transpose). Output is $\{U, W, V\}$.

3. An option:

- The default value **`Automatic`** of the option **`Tolerance`** keeps only singular values larger than 100×10^{-p}, where p is **`Precision[m]`**. **`Tolerance`** → **`t`** keeps only singular values that are at least **`t`** times the largest singular value. **`Tolerance`** → **`0`** returns all singular values (the total number of singular values is the smaller of the numbers of rows and columns).

4. Largest singular values and generalized singular values:

- **`SingularValueList[m, k]`** Calculate the **`k`** largest singular values.
- **`SingularValueList[{m, a}]`** Calculate the generalized singular values of **`m`** with respect to **`a`**.

Examples

1. Singular values. The singular values of a matrix M are the square roots of the eigenvalues of the matrix $M^\dagger M$:

```
m={{6,2,3},{2,7,5},{4,2,5}};

SingularValueList[m//N]     {12.1048,4.75064,1.70418}

N[Sqrt[Eigenvalues[m†.m]]]     {12.1048,4.75064,1.70418}
```

Only non-zero singular values are returned by **`SingularValueList`**:

```
n={{7,7,2,7},{2,5,0,7},{8,7,8,3},{5,6,4,5}};

SingularValueList[n//N]     {21.5225,7.09914,1.84001}
```

By giving **`Tolerance`** the value 0 we get all singular values:

```
SingularValueList[n//N,Tolerance → 0]

{21.5225,7.09914,1.84001,1.61343 × 10^-16}
```

2. Singular value decomposition. Here is an example of this decomposition:

```
Map[MatrixForm,{u,w,v}=SingularValueDecomposition[m//N]]
```

```
{ -0.516443   0.629389  -0.580652     12.1048   0.         0.
  -0.672542  -0.717852  -0.179933  ,  0.       4.75064    0.       ,
  -0.53007    0.297588   0.79402      0.       0.         1.70418

  -0.542264   0.743264   -0.391801
  -0.561826  -0.667491   -0.488678 }
  -0.624741  -0.0448685   0.779542
```

The following verifies the decomposition:

```
Chop[m-u.w.v†]     {{0,0,0},{0,0,0},{0,0,0}}

Chop[u.u†]     {{1.,0,0},{0,1.,0},{0,0,1.}}

Chop[v.v†]     {{1.,0,0},{0,1.,0},{0,0,1.}}
```

Applications

1. (Condition numbers) Relative to a matrix norm $\|M\|$, the condition number of an invertible matrix M is $\|M\|\|M^{-1}\|$. See Section 50.4 for more information about condition numbers. A condition number is ≥ 1; a large condition number indicates sensitivity to round-off errors. Because $\|M\|_2$ is the largest singular value of M and $\|M^{-1}\|_2$ is the reciprocal of the smallest singular value of M, then the 2-norm condition number is the maximum singular value divided by the minimum singular value:

```
cond[m_]:=With[{s=SingularValueList[m//N,Tolerance → 0]},
  First[s]/Last[s]]
```

For example, consider the condition numbers of the first few Hilbert matrices:

```
Table[cond[HilbertMatrix[i]],{i,1,6}]

{1.,19.2815,524.057,15513.7,476607.,1.49511 × 10^7}
```

The condition numbers grow rapidly and they are large even for small Hilbert matrices. This indicates numerical difficulties associated with Hilbert matrices.

90.8 Decompositions

Commands

1. Decompositions into triangular matrices:

- **`LUDecomposition[m]`** PLU decomposition of a square matrix. For matrix M, the decomposition is $PM = LU$, where L is unit lower triangular (with ones on the diagonal), U is upper triangular, and P is a permutation matrix. Output is $\{K, p, c\}$, where matrix K contains both L and U, p is a permutation vector, that is, a list specifying rows used for pivoting, and c is the L^∞ condition number of m (however, for exact matrices with no decimal points, c is 1).

- **`CholeskyDecomposition[m]`** Cholesky decomposition of a Hermitian, positive definite matrix. For matrix M, the decomposition is $M = U^\dagger U$, where U is upper triangular. Output is U.
- **`HermiteDecomposition[m]`** Hermite decomposition of an integer or rational (real or complex) matrix. For matrix M, the decomposition satisfies $UM = R$ where U is unimodular (a real square matrix whose determinant is ± 1) and R is upper triangular. Output is U.

2. Orthogonal decompositions:

- **`SingularValueDecomposition[m]`** Singular value decomposition of a (possibly rectangular) matrix. For matrix M, the decomposition is $M = UWV^\dagger$ where U and V are orthonormal and W is diagonal with singular values as the diagonal elements († means conjugate transpose). Output is $\{U, W, V\}$. See Command 90.7.2.
- **`QRDecomposition[m]`** QR decomposition of a numerical matrix. For matrix M, the decomposition is $M = Q^\dagger R$, where Q is orthonormal and R is upper triangular. Output is $\{Q, R\}$.

3. Decompositions related to eigenvalue problems:

- **`JordanDecomposition[m]`** Jordan decomposition of a square matrix. For matrix M, the decomposition is $M = SJS^{-1}$, where S is a similarity matrix and J is the Jordan canonical form of M. Output is $\{S, J\}$.
- **`SchurDecomposition[m]`** Schur decomposition of a square, numerical matrix with at least one entry that has a decimal point. For matrix M, the decomposition is $M = QTQ^\dagger$, where Q is orthonormal and T is block upper triangular. Output is $\{Q, T\}$.
- **`HessenbergDecomposition[m]`** Hessenberg decomposition of a square, numerical matrix with at least one entry that has a decimal point. For matrix M, the decomposition is $M = PHP^\dagger$, where P is a unitary matrix ($P^\dagger = P^{-1}$) and H is a Hessenberg matrix (an upper triangular matrix with also a nonzero diagonal below the main diagonal). Output is $\{P, H\}$.

Examples

1. Decompositions into triangular matrices. As an example, we consider the PLU decomposition:

```
m={{2.,7,5},{6,2,3},{4,2,5}};
```

```
Map[MatrixForm,{lu,perm,cond}=LUDecomposition[m]]
```

```
  ⎛   6.         2.        3.    ⎞   ⎛2⎞
{ ⎜0.333333   6.33333      4.    ⎟ , ⎜1⎟ ,9.42857 }
  ⎝0.666667   0.105263  2.57895  ⎠   ⎝3⎠
```

The matrix **`lu`** contains both the L and the U matrix, **`perm`** is a permutation vector specifying rows used for pivoting, and **`cond`** is the L^∞ condition number of **`m`**. In the following way we can extract the L and U matrices from the **`lu`** matrix:

```
l=Table[If[j<i,lu[[i,j]],If[j==i,1,0]],{i,3},{j,3}];

u=Table[If[j ≥ i,lu[[i,j]],0],{i,3},{j,3}];

{MatrixForm[l],MatrixForm[u]}
```

```
{ ( 1          0          0 )   ( 6.    2.        3.      ) }
{ ( 0.333333   1          0 ) , ( 0     6.33333   4.      ) }
{ ( 0.666667   0.105263   1 )   ( 0     0         2.57895 ) }
```

The following calculation verifies the PLU decomposition:

```
m1=m[[perm]]      {{6,2,3},{2.,7,5},{4,2,5}}

m1-l.u      {{0.,0.,0.},{0.,0.,0.},{0.,0.,0.}}
```

Once the PLU decomposition of `m` is ready, we can solve a system of linear equations with coefficient matrix `m`. Define `b`, the constant vector, and then apply two backsolves:

```
b={2,4,1};

y=LinearSolve[l,b[[perm]]]      {4.,0.666667,-1.73684}

LinearSolve[u,y]      {0.826531,0.530612,-0.673469}
```

This solution is, of course, the same as we get directly with **`LinearSolve`**:

```
LinearSolve[m,b]      {0.826531,0.530612,-0.673469}
```

90.9 Linear Systems

Commands

1. Solving equations written explicitly:
    - **`lhs == rhs`** An equation with left-hand-side **`lhs`** and right-hand-side **`rhs`** (after you have written the two equal signs **`==`**, *Mathematica* replaces them with the single symbol **`==`**).
    - **`eqns =`** {eqn$_1$, eqn$_2$, ... } A system of equations with the name **`eqns`**.
    - **`Solve[eqns]`** Solve the equations **`eqns`** for the symbols therein.
    - **`Solve[eqns, vars]`** Solve the equations **`eqns`** for the variables in list **`vars`**.
2. More about equations written explicitly:
    - **`Reduce[eqns, vars]`** Give a full analysis of the solution.
    - **`Solve[eqns, vars, elims]`** Solve **`eqns`** for **`vars`**, eliminating **`elims`**.
    - **`Eliminate[eqns, elims]`** Eliminate **`elims`** from **`eqns`**.
3. Solving equations defined by matrices:
    - **`LinearSolve[m, v]`** Solve the linear system **`m.vars == v`**.
    - **`Solve[m.vars == v]`** Solve the linear system **`m.vars == v`**.

- If it is possible that the system has more than one solution, it is better to use **`Solve`**, as **`LinearSolve`** only gives one solution (with no warning).

4. More about equations defined by matrices:

- **`LinearSolve[m, v]`** Solve a tridiagonal system; use **`Band`** and **`SparseArray`** to generate the tridiagonal matrix.
- **`f = LinearSolve[m]`** Give a function **`f`** for which **`f[v]`** solves the system **`m.x == v`**.
- **`LeastSquares[m, v]`** Give the least-squares solution of the equations **`m.x == v`**.
- **`RowReduce[a]`** Do Gauss-Jordan elimination to the augmented matrix **`a`** to produce the reduced row echelon form, where the last column is the solution of the system.

5. Conversion between the two forms of linear equations:

- **`eqns = Thread[m.vars == v]`** Generate explicit equations from a coefficient matrix **`m`** and a constant vector **`v`** by using the list of variables **`vars`**.
- **`{v, m} = CoefficientArrays[eqns, vars]`** Give the constant vector **`v`** and the coefficient matrix **`m`** from the given linear equations **`eqns`** containing variables **`vars`**; the coefficients correspond with the system **`v + m.vars == 0`**.

Examples

1. Solving equations written explicitly. If the system does not have any symbols other than the variables for which the system has to be solved, we need not declare the variables in **`Solve`**:

```
sol=Solve[{2x+5y+z==2, 3x+4y+3z==2, 6x+y+2z==5}]
```

$\left\{\left\{x \to \frac{47}{49}, y \to \frac{5}{49}, z \to -\frac{3}{7}\right\}\right\}$

`N[sol]` `{{x → 0.959184,y → 0.102041,z → -0.428571}}`

Here is an example where we declare the variables:

```
eqns={2x+5y+z==2, 3x+4y+3z==2, 6x+y+2z==5};
```

```
vars={x,y,z};
```

`sol=Solve[eqns,vars]` $\left\{\left\{x \to \frac{47}{49}, y \to \frac{5}{49}, z \to -\frac{3}{7}\right\}\right\}$

`Solve` gives the solution in the form of transformation rules. If we want a list of the values of the variables, we can write

`vars/.sol[[1]]` $\left\{\frac{47}{49}, \frac{5}{49}, -\frac{3}{7}\right\}$

To check the solution, write

`eqns/.sol` `{{True,True,True}}`

(Note that for an inexact solution the test may yield False for some equations due to round-off errors.) If a solution does not exist, we get an empty list:

`Solve[{x+2y==2,2x+4y==1}]` `{}`

If an infinite number of solutions exist, we get all of them:

```
Solve[{x+2y==2,2x+4y==4}]
```

$$\{\{\mathtt{x} \to \mathtt{2-2y}\}\}$$

This means that x has the value $2 - 2y$, while y can be arbitrary.

The system may contain symbols:

```
eqns2={2x+5y==3,3x+d y==2};
```

```
Simplify[Solve[eqns2,{x,y}]]
```

$$\left\{\left\{\mathtt{x} \to \frac{\mathtt{10-3d}}{\mathtt{15-2d}}, \mathtt{y} \to \frac{\mathtt{5}}{\mathtt{15-2d}}\right\}\right\}$$

Note that this is a *generic* solution that is valid for most values of the parameter **`d`**. To get a full analysis of the equations, use **`Reduce`**; see Example 2.

2. More about equations written explicitly. Consider again the system **`eqns2`** that contains a parameter. To get a full analysis of the equations, we use **`Reduce`**. The result is a logical statement where, for example, `&&` means logical AND and || means logical OR:

```
Reduce[eqns2,{x,y}]
```

$$\mathtt{-15+2d} \neq \mathtt{0}\ \mathtt{\&\&}\ \mathtt{x==}\frac{\mathtt{-10+3d}}{\mathtt{-15+2d}}\ \mathtt{\&\&}\ \mathtt{y==}\frac{\mathtt{1}}{\mathtt{5}}\mathtt{(3-2\ x)}$$

We can also solve systems that contain inequalities:

```
Reduce[{x+y ≥ a,x−y ≤ b},{x,y},Reals]
```

$$\left(\mathtt{x} \leq \frac{\mathtt{a+b}}{\mathtt{2}}\ \mathtt{\&\&}\ \mathtt{y} \geq \mathtt{a-x}\right) \| \left(\mathtt{x} > \frac{\mathtt{a+b}}{\mathtt{2}}\ \mathtt{\&\&}\ \mathtt{y} \geq \mathtt{-b+x}\right)$$

The following equations contain the parameter **`d`**, which we would like to eliminate:

```
eqns={x+y−z==d, x−2y+z==−d, −x+y+z==2d};

vars={x,y,z};
```

```
Solve[eqns,vars,d]
```

$$\left\{\left\{\mathtt{y} \to \mathtt{2x},\ \ \mathtt{z} \to \frac{\mathtt{5x}}{\mathtt{3}}\right\}\right\}$$

Alternatively, we can use **`Eliminate`**. The result is then expressed as a logical expression:

```
Eliminate[eqns,d]
```

$$\mathtt{2x==y\ \&\&\ 5y==6z}$$

3. Solving equations defined by matrices. We continue with the same system that we considered in Example 1:

```
m={{2,5,1},{3,4,3},{6,1,2}};

v={2,2,5};
```

```
sol=LinearSolve[m,v]
```

$$\left\{\frac{47}{49}, \frac{5}{49}, -\frac{3}{7}\right\}$$

We can check the solution:

```
m.sol−v
```

$$\{0,0,0\}$$

We can also use **`Solve`** if we form an equation with variables:

```
Solve[m.{x,y,z}==v]
```

$$\left\{\left\{\mathtt{x} \to \frac{47}{49}, \mathtt{y} \to \frac{5}{49}, \mathtt{z} \to -\frac{3}{7}\right\}\right\}$$

If a solution does not exist, **`LinearSolve`** writes the command as such:

```
LinearSolve[{{1,2},{2,4}},{2,1}]
```

```
LinearSolve[{{1,2},{2,4}},{2,1}]
```

In the Messages window, we get the following message:

```
LinearSolve::nosol:Linear equation encountered that has no
solution.⟩⟩
```

If an infinite number of solutions exist, we are given one of them (with no warning):

```
LinearSolve[{{1,2},{2,4}},{2,4}]      {2,0}
```

The system may contain symbols:

```
Simplify[LinearSolve[{{2,5},{3,d}},{3,2}]]
```

$\left\{\frac{10-3d}{15-2d}, \frac{5}{15-2d}\right\}$

4. More about equations defined by matrices. We solve a tridiagonal system. First, we define the diagonals and the constant vector:

```
sub={1,1}; main={4,4,4}; super={2,2}; v={6,4,7};
```

Then we form the coefficient matrix:

```
m=SparseArray[{Band[{2,1}] → sub,Band[{1,1}] → main,Band[{1,2}] →
  super}]

SparseArray[<7>,{3,3}]
```

We can check that the matrix is correct:

```
m//MatrixForm
```

$$\begin{pmatrix} 4 & 2 & 0 \\ 1 & 4 & 2 \\ 0 & 1 & 4 \end{pmatrix}$$

Last, we solve the system:

```
LinearSolve[m,v]
```

$\left\{\frac{5}{3}, -\frac{1}{3}, \frac{11}{6}\right\}$

In the following way get a function that can then be applied to get the solution of a system by giving the right-hand-side vector as an argument:

```
f=LinearSolve[m]

LinearSolveFunction[{3,3},<>]
```

We solve the system with three different right-hand-side vectors:

```
v1={2,2,5}; v2={1,4,3}; v3={4,2,6};

{f[v1],f[v2],f[v3]}
```

$\left\{\left\{\frac{2}{3}, -\frac{1}{3}, \frac{4}{3}\right\}, \left\{-\frac{1}{8}, \frac{3}{4}, \frac{9}{16}\right\}, \left\{\frac{4}{3}, -\frac{2}{3}, \frac{5}{3}\right\}\right\}$

Some linear systems do not have a solution; typically, we then have more equations than variables. In such a situation we can get a least squares solution that minimizes the norm $\|m.x - v\|_2$:

```
LeastSquares[{{1,2},{2,4}},{2,1}]        {4/25, 8/25}
```

The same solution can also be got with the pseudoinverse (compare with the solution $x = M^{-1}v$ of a usual system $M.x = v$):

```
PseudoInverse[{{1,2},{2,4}}].{2,1}        {4/25, 8/25}
```

See Sections 5.7 and 5.8 or Chapter 52 for definitions and more information on the pseudoinverse and least squares solution.

Next we apply Gauss-Jordan elimination to the augmented matrix to produce the reduced row echelon form, where the last column is the solution of the system:

```
n=Append[m^T,v]^T       {{4,2,0,6},{1,4,2,4},{0,1,4,7}}

r=RowReduce[n]       {{1,0,0,5/3}, {0,1,0, -1/3},{0,0,1,11/6}}

sol=r[[All,4]]       {5/3, -1/3, 11/6}
```

5. Conversion between the two forms of linear equations. First we go from matrices to equations:

```
m={{2,5,1},{3,4,3},{6,1,2}};

v={2,2,5};

eqns=Thread[m.{x,y,z}==v]

{2x+5y+z==2, 3x+4y+3z==2, 6x+y+2z==5}
```

Then we go from equations to matrices:

```
{v1,m1}=CoefficientArrays[eqns,{x,y,z}]

{SparseArray[<3>,{3}],SparseArray[<9>,{3,3}]}

Normal[%]      {{-2,-2,-5},{{2,5,1},{3,4,3},{6,1,2}}}
```

We check that we got the correct matrices:

```
Thread[v1+m1.{x,y,z}==0]

{-2+2x+5y+z==0, -2+3x+4y+3z==0, -5+6x+y+2z==0}
```

Applications

1. (Cramer's rule for a linear system) Cramer's rule is a traditional but inefficient way to solve linear systems. In this method, the value of the ith variable is got by dividing two determinants: the numerator is the determinant of the coefficient matrix where the ith column is replaced by the right-hand-side vector, and the denominator is the determinant of the original coefficient matrix. The following code gives a program for this method:

```
cramersRule[m_,v_]:=Module[{a,d=Det[m]},
 Table[a=m; a[[All,i]]=v; Det[a]/d, {i,Length[m]}]]
```

Here is a small example:

```
cramersRule[{{1,2},{2,-1}},{7,4}]      {3,2}
```

The same result is got with **`LinearSolve`**:

```
LinearSolve[{{1,2},{2,-1}},{7,4}]      {3,2}
```

2. (Gauss−Seidel method for a linear system) Consider a diagonally dominant linear system with n variables x_i. From the ith equation, solve x_i, $i = 1, \ldots, n$. Rename the left-hand-side variables as x_i^{new}. In the right-hand-side of the ith equation, in place of x_j, $j = 1, \ldots, i-1$, write x_j^{new} and in place of x_j, $j = i+1, \ldots, n$, write x_j^{old}. In this way, we get iteration equations. Start from, say, the zero vector and then iteratively calculate new values from the iteration equations until convergence. This is the so-called Gauss−Seidel method. The following program implements this method.

```
GaussSeidel[m_?MatrixQ,v_?VectorQ,ϵ_:10^ − 15,iters_:500]:=
   Module[{n=Length[v],xx,eqns,iterx,xold,xnew},
     xx=Array[x,n];
     eqns=Thread[m.xx==v];
     iterx=xx/.Table[Solve[eqns[[i]],x[i]][[1,1]],{i,n}];
     xold=xnew=ConstantArray[0.,n];
     Do[xnew=Table[xnew[[j]]=iterx[[j]]/.Thread[xx → xnew],{j,n}];
      If[Norm[xold − xnew]<ϵ,Break[],xold=xnew],{iters}];
      xnew]
```

Here, the default value of ϵ is 10^{-15} and, by default, we do at most 500 iterations. As an example, we generate a diagonally dominant system:

```
m=RandomReal[{0,1},{10,10}];
v=RandomReal[{0,1},{10}];
Do[m[[i,i]]=2,{i,10}];
```

Then we solve the system with the Gauss−Seidel method and, to compare, also with the built-in command:

```
GaussSeidel[m,v]

{0.201183,0.327176,-0.256345,0.157003,-0.0376672,-0.0808366,
0.156302,0.176122,-0.307437,0.388922}

LinearSolve[m,v]
```

```
{0.201183,0.327176,-0.256345,0.157003,-0.0376672,-0.0808366,
0.156302,0.176122,-0.307437,0.388922}
```

```
Chop[%%-%]        {0,0,0,0,0,0,0,0,0,0}
```

3. (Newton's method for a nonlinear system) Consider the system $f(x) = 0$ of nonlinear equations (here, f and x are vectors). In an iterative solution process, let the starting point be x_0 and let x_n be the approximation of the solution of the system that we get at the nth iteration. Let f_n be the value of $f(x)$ at x_n and J_n the Jacobian of the $f(x)$ at x_n. With Newton's method, the next approximation is calculated from $x_{n+1} = x_n - {J_n}^{-1} f_n$. However, matrix inversion should be avoided whenever possible. Thus, instead we do as follows. Denote $\delta_x = x_{n+1} - x_n$. Then $\delta_x = -{J_n}^{-1} f_n$ or $J_n \delta_x = -f_n$. So, we first solve the linear system $J_n \delta_x = -f_n$ for δ_x and then calculate $x_{n+1} = x_n + \delta_x$. The stopping criterion is $\|x_{n+1} - x_n\|_2 < \epsilon$. In the following, we have a program for Newton's method.

```
newtonSolveSystem[f_List,vars_List,vars0_List,eps_:10^-6,iters_:20]
 :=With[{jac=D[f,{vars}]},
  FixedPointList[#+LinearSolve[jac/.Thread[vars → #],-f/.
  Thread[vars → #]]&,N[vars0],iters,SameTest → (Norm[#1−#2]<eps&)]]
```

Here, the default value of ϵ is 10^{-6} and, by default, we do at most 20 iterations. As an example, let us find a point where $x^2 + y^2 = 1$ and $y = \sin(x)$:

```
f={x^2+y^2-1,Sin[x]-y}; vars={x,y};

newtonSolveSystem[f,vars,{2,2}]
```

```
{{2.,2.},{0.870782,1.37922},{0.880513,0.771102},{0.745682,0.685211},
{0.739148,0.673673},{0.739085,0.673612},{0.739085,0.673612}}
```

With **`FindRoot`**, we get the same solution:

```
FindRoot[f,{{x,2},{y,2}}]        {x → 0.739085,y → 0.673612}
```

4. (Points of convergence of Newton's method) We consider the same nonlinear system as in Application 2. First, we find points near to the origin from where Newton's method converges to the point $(0.739085, 0.673612)$:

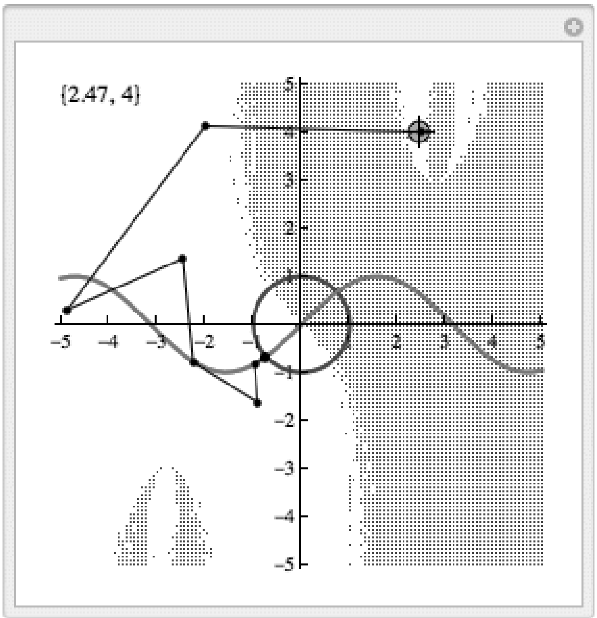
```
pp={};Do[
  sol=Last[newtonSolveSystem[f,vars,{x0,y0}]];
  If[Norm[sol-{0.739085,0.673612}]<10^-5,pp={pp,{x0,y0}}],
  {x0,-5,5,0.08},{y0,-5,5,0.08}];
```

We plot these points and the two equations (but do not yet show the combined plot):

```
gg=Show[ListPlot[Partition[Flatten[pp],2],AspectRatio → Automatic,
   PlotStyle → PointSize[Tiny],PlotRange → {{-5.1,5.1},{-5.1,5.1}},
  Ticks → {Range[-5,5],Range[-5,5]},ImageSize → 259],
  ContourPlot[Evaluate[Thread[f==0]],{x,-5,5},{y,-5,5},
  ContourStyle → {{Thick,Blue},{Thick,Red}}]];
```

The following manipulation shows how Newton's method proceeds when the starting point is varied with the mouse. By starting from the small light-blue points, Newton's method converges to the point $(0.739085, 0.673612)$. The other point of convergence is $(-0.739085, -0.673612)$.

```
Manipulate[DynamicModule[{sol},
 sol=newtonSolveSystem[f,vars,start];
 Show[gg,Graphics[{PointSize[Medium],Point[sol],Thickness[Medium],
   Line[sol],Style[Text[start,{-5,5},{-1,1}],12]}]]],
 {{start,{2.47,4}},Locator},SaveDefinitions → True]
```



5. (Linear least squares for data) Consider the linear least squares problem. We have the data (x_i, f_i), $i = 1, \ldots, n$. We would like to get an approximation of the form $c_1 h_1(t) + \ldots + c_k h_k(t)$ where c_j is an unknown parameter to be estimated and h_j is a given basis function. Let the vector c contain the unknown parameters and the vector h the basis functions. We would like to minimize the sum of the square of the difference between the f_i values and the values of the approximating function at the x_i points. Let the vector x contain the x_i values and the vector f the f_i values. Let the ith row of the matrix X contain the values of the basis functions at x_i. The least squares estimates of the parameters are $c = (X^\mathsf{T} X)^{-1} X^\mathsf{T} f$. However, as matrix inversion should be avoided, the parameters are solved from the linear equations $X^\mathsf{T} X c = X^\mathsf{T} f$, the so-called normal equations. The following program uses this method:

```
lsData[x_List,f_List,h_List,t_]:=With[{X=h/.t → #&/@x},
  LinearSolve[X^T.X,X^T.f].h]
```

As an example, we first generate some random data:

```
x=Range[0,50];SeedRandom[2];

rand=RandomReal[NormalDistribution[0,1],51];

f=2+x-0.004x^2+2rand;
```

We calculate a quadratic least squares fit with our program and also with **`Fit`** and **`LeastSquares`**:

```
lsData[x,f,{1,t,t^2},t]       1.48998+1.0506t-0.00531772t^2

Fit[{x,f}^T,{1,t,t^2},t]      1.48998+1.0506t-0.00531772t^2

LeastSquares[{1,#,#^2}&/@x,f]      {1.48998,1.0506,-0.00531772}
```

6. (Linear least squares for functions) Consider the linear least squares problem for functions. We have a function $f(t)$ for which we would like to get an approximation, on the interval (a, b), of the form $c_1h_1(t) + \ldots + c_kh_k(t)$ where c_j is an unknown parameter to be estimated and h_j is a given basis function. We would like to minimize the integral of the square of the difference between the function and the approximation on the interval considered. Let the vector c contain the unknown parameters and the vector h the basis functions. The least squares estimates of the parameters can then be solved from the linear equations $\left(\int_a^b h \otimes h \, dt\right) c = \int_a^b fhdt$, where $\otimes$ means outer product. The following program uses this method:

```
lsFunction[f_,a_,b_,h_List,t_]:=

  LinearSolve[NIntegrate[KroneckerProduct[h,h],{t,a,b}],

  NIntegrate[f h,{t,a,b}]].h
```

As an example, we consider the following function:

```
f=(1+Erf[t/Sqrt[2]])/2;
```

For this function, we calculate a sixth-degree least squares approximation on $(0, 2)$:

```
appr=lsFunction[f,0,2,t^Range[0,6],t]

0.500019+0.398426t+0.00319491t^2-0.0741471t^3+0.00780805t^4+

0.00784075t^5-0.00179815t^6
```

90.10 Linear Programming

Commands

1. Solving linear optimization problems written explicitly:

- **`Minimize[{obj, cons}, vars]`** Give the global minimum of **`obj`** subject to constraints **`cons`** with respect to variables **`vars`**; we also have **`Maximize`**.

- **Minimize**/**Maximize** uses **NMinimize**/**NMaximize** if the problem contains a decimal point.
- **MinValue[{obj, cons}, vars]** Give only the minimum value of **obj**; we also have **MaxValue**.
- **ArgMin[{obj, cons}, vars]** Give only the point of minimum; we also have **ArgMax**.

2. Solving linear optimization problems defined by matrices:

- **LinearProgramming[c, m, b]** Minimize **c.x** subject to **m.x** $\geq$ **b** and **x** $\geq$ **0**.
- **LinearProgramming[c, m, {{b_1, s_1}, {b_2, s_2}, ... }]** The ith constraint is m_i.x $\leq$ b_i, m_i.x == b_i, or m_i.x $\geq$ b_i according to whether s_i is -1, 0, or 1.
- **LinearProgramming[c, m, b, low]** Use the restriction x_i $\geq$ **low** for all **i**.
- **LinearProgramming[c, m, b, {low_1, low_2, ... }]** Use the restrictions x_i $\geq$ low_i.
- **LinearProgramming[c, m, b, {{low_1, up_1}, {low_2, up_2}... }]** Use the restrictions $low_i \leq x_i \leq up_i$.
- **LinearProgramming[c, m, b, Method → "InteriorPoint"]** Use the interior point method (it is fast for sparse machine-precision problems).

3. Solving integer linear optimization problems written explicitly:

- {**Minimize[{obj, cons}, vars, Integers]** Restrict all variables to be integer-valued.
- **Minimize[{obj, cons, {x_1,x_2,...} ∈ Integers}, vars]** Restrict single variables to be integer-valued.

4. Solving integer linear optimization problems defined by matrices:

- **LinearProgramming[c, m, b, low, Integers]** Restrict all variables to be integer-valued.
- **LinearProgramming[c, m, b, low, {dom_1, dom_2, ... }]** Use the restrictions x_i ∈ dom_i, where each domain is **Reals** or **Integers**.
- If the problem does not contain a decimal point, a warning appears.

Examples

1. Solving linear optimization problems written explicitly.

```
obj=2x+3y; cons={x+y ≥ 4,x+3y ≥ 5,x ≥ 0,y ≥ 0}; vars={x,y};
```

`Minimize[{obj,cons},vars]` $\left\{\frac{17}{2}, \left\{x \to \frac{7}{2}, y \to \frac{1}{2}\right\}\right\}$

Here the minimum value of the objective function is 17/2.

2. Solving linear optimization problems defined by matrices. We solve the problem in Example 1:

```
c={2,3}; m={{1,1},{1,3}}; b={4,5};
```

`sol=LinearProgramming[c,m,b]` $\left\{\frac{7}{2}, \frac{1}{2}\right\}$

`c.sol` $\frac{17}{2}$

3. Solving integer linear optimization problems written explicitly. Consider again the problem in Example 1 but now restrict the variables to be integer-valued. The problem can be solved in two ways:

```
Minimize[{obj,cons},vars,Integers]        {9,{x → 3,y → 1}}
```

```
Minimize[{obj,cons,vars ∈ Integers},vars]       {9,{x → 3,y → 1}}
```

Write the symbol ∈ as $\boxed{\text{ESC}}$el$\boxed{\text{ESC}}$.

4. Solving integer linear optimization problems defined by matrices. Consider again the problem in Example 2 but now restrict the variables to be integer-valued:

```
sol=LinearProgramming[c,m,b,0,Integers]      {3,1}
```

In the Messages window, we get the following warning:

```
LinearProgramming::lpip:Warning: Integer linear programming will
use a machine-precision approximation of the inputs. ⟩⟩
```

To get rid of the warning, add a decimal point into the problem:

```
sol=LinearProgramming[c,m,b,0.,Integers]      {3,1}
```

Applications

1. (A transportation problem in explicit form) See Chapter 68 for definitions and more information about linear programming. Consider the following transportation problem (cf. [Rus09, pp. 754–756]). Supplies of plants 1 and 2, demands of cities 1, 2, and 3, and costs between the plants and the cities are as follows:

```
supply={40,60}; demand={35,40,25}; costs={{4,9,6},{5,3,7}};
```

For example, to transport one unit from plant 1 to city 3 costs $6. The problem is to minimize the total cost of transportation. Let $x_{i,j}$ be the amount transported from plant i to city j:

```
vars=Table[x_{i,j},{i,2},{j,3}]
```

```
{{x_{1,1},x_{1,2},x_{1,3}},{x_{2,1},x_{2,2},x_{2,3}}}
```

The objective function is

```
obj=Flatten[costs].Flatten[vars]
```

```
4x_{1,1}+9x_{1,2}+6x_{1,3}+5x_{2,1}+3x_{2,2}+7x_{2,3}
```

The supply, demand, and nonnegativity constraints are as follows:

```
sup=Thread[Map[Total,vars] ≤ supply]
```

```
{x_{1,1}+x_{1,2}+x_{1,3} ≤ 40,x_{2,1}+x_{2,2}+x_{2,3} ≤ 60}
```

```
dem=Thread[Total[vars] ≥ demand]
```

$$\{x_{1,1} + x_{2,1} \geq 35, x_{1,2} + x_{2,2} \geq 40, x_{1,3} + x_{2,3} \geq 25\}$$

```
non=Thread[Flatten[vars] ≥ 0]
```

$$\{x_{1,1} \geq 0, x_{1,2} \geq 0, x_{1,3} \geq 0, x_{2,1} \geq 0, x_{2,2} \geq 0, x_{2,3} \geq 0\}$$

Then we solve the problem:

```
sol=Minimize[{obj,sup,dem,non},Flatten[vars]]
```

$$\{430, \{x_{1,1} \to 15, x_{1,2} \to 0, x_{1,3} \to 25, x_{2,1} \to 20, x_{2,2} \to 40, x_{2,3} \to 0\}\}$$

2. (A transportation problem in matrix form) Consider the transportation problem of Application 1 (cf. [Rus09, p. 758]). First, generate the coefficients that correspond with the supply and demand constraints:

```
(sup=SparseArray[Band[{1,1}] → Table[ConstantArray[1,{1,3}],{2}]])
//MatrixForm
```

$$\begin{pmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 \end{pmatrix}$$

```
(dem=ArrayFlatten[{Table[IdentityMatrix[3],{2}]}])//MatrixForm
```

$$\begin{pmatrix} 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 \end{pmatrix}$$

Build the coefficient matrix:

```
(m=Join[sup,dem])//MatrixForm
```

$$\begin{pmatrix} 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 1 \\ 1 & 0 & 0 & 1 & 0 & 0 \\ 0 & 1 & 0 & 0 & 1 & 0 \\ 0 & 0 & 1 & 0 & 0 & 1 \end{pmatrix}$$

Form the `b` vector:

```
b={Join[supply,demand],Join[ConstantArray[-1,Length[supply]],
ConstantArray[1,Length[demand]]]}^T
```

```
{{40,-1},{60,-1},{35,1},{40,1},{25,1}}
```

Solve the problem:

```
sol=LinearProgramming[Flatten[costs],m,b]      {15,0,25,20,40,0}
```

```
Flatten[costs].sol      430
```

3. (A knapsack problem in explicit form) Let us solve a knapsack problem in which the benefits of five items are 14, 10, 15, 8, and 9 and the corresponding weights are 6, 8, 5, 6, and 4. What is the optimal collection of items when we want to maximize the total benefit subject to the constraint that the total weight has to be at most 18? Let x_i be 1 if the ith item is included and 0 otherwise. $0-1$ variables can be formulated in *Mathematica* by constraining the variables in the interval $[0, 1]$ and requiring that the variables are integers. Write the following:

```
benefits={14,10,15,8,9};

weights={6,8,5,6,4};

vars=Table[x_i,{i,5}];
```

```
{val,point}=Maximize[{benefits.vars,weights.vars ≤ 18,

Thread[0 ≤ vars ≤ 1]},vars,Integers]
```

```
{38, {x_1 → 1,x_2 → 0,x_3 → 1,x_4 → 0,x_5 → 1}}
```

It is optimal to take the first, third, and fifth items; the total benefit is then 38. The total weight is as follows:

```
weights.vars/.point      15
```

This means that 3 weight units are unused.

4. (A knapsack problem in matrix form) Let us solve the knapsack problem of Application 3. Write the following:

```
sol=LinearProgramming[-benefits,-{weights},{-18.},Table[{0,1},{5}],

Integers]
```

```
{1,0,1,0,1}
```

The corresponding benefit and total weight are

```
{benefits.sol,weights.sol}      {38,15}
```

5. (Ready-to-use examples) *Mathematica* has 138 ready-to-use examples of linear programming:

```
ExampleData["LinearProgramming"]//Length      138
```

By executing **`ExampleData["LinearProgramming"]`** we get a list of all of them. Here is one of them whose name is afiro:

```
{c,m,b,n}=ExampleData[{"LinearProgramming","afiro"}]
```

```
{{0,-0.4,0,0,0,0,0,0,0,0,0,0,-0.32,0,0,0,-0.6,0,0,0,0,0,0,0,0,0,0,
0,-0.48,0,0,10.},SparseArray[<83>,{27,32}],{{0.,0},{0.,0},{80.,-1},
{0.,-1},{0.,0},{0.,0},{80.,-1},{0.,-1},{0.,-1},{0.,-1},{0.,0},{0.,0},
{500.,-1},{0.,-1},{0.,0},{44.,0},{500.,-1},{0.,-1},{0.,-1},{0.,-1},
{0.,-1},{0.,-1},{0.,-1},{0.,-1},{0.,-1},{310.,-1},{300.,-1}},{{0,∞},
{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},
{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},
{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},{0,∞},
{0,∞}}}
```

Here, **c** is the coefficient vector of the objective function, **m** is the constraint matrix, **b** is the right-hand-side of the constraints, and **n** is the non-negativity constraints. The solution of the problem is as follows:

```
sol=LinearProgramming[c,m,b]
```

```
{80.,25.5,54.5,84.8,18.2143,0.,0.,0.,0.,0.,0.,0.,18.2143,0.,
19.3071,500.,475.92,24.08,0.,215.,0.,0.,0.,0.,0.,0.,0.,0.,
339.943,383.943,0.,0.}
```

```
c.sol    -464.753
```

For linear programming examples, we can ask for the following information:

```
ExampleData[{"LinearProgramming","afiro"},"Properties"]
```

```
{Collection,ConstraintMatrix,Dimensions,Equations,
LinearProgrammingData,Name,Source}
```

Here are some of the properties:

```
ExampleData[{"LinearProgramming","afiro"},#]&/@{"Dimensions",
"Name","Collection","Source"}
```

```
{{27,32},afiro,Netlib,http://www.netlib.org/lp/data/afiro}
```

Next, we ask for the explicit equations:

```
{{obj,cons},vars}=ExampleData[{"LinearProgramming","afiro"},
"Equations"];
```

For example, the objective function is as follows:

```
obj
```

$-0.4X02_{MPS}-0.32X14_{MPS}-0.6X23_{MPS}-0.48X36_{MPS}+10.X39_{MPS}$

We can then solve the problem:

```
Minimize[{obj,cons},vars]
```

{-464.753, {X01$_{\text{MPS}}$ → 80., X02$_{\text{MPS}}$ → 25.5, X03$_{\text{MPS}}$ → 54.5, X04$_{\text{MPS}}$ → 84.8,
X06$_{\text{MPS}}$ → 18.2143, X07$_{\text{MPS}}$ → 0., X08$_{\text{MPS}}$ → 0., X09$_{\text{MPS}}$ → 0., X10$_{\text{MPS}}$ → 0.,
X11$_{\text{MPS}}$ → 0., X12$_{\text{MPS}}$ → 0., X13$_{\text{MPS}}$ → 0., X14$_{\text{MPS}}$ → 18.2143, X15$_{\text{MPS}}$ → 0.,
X16$_{\text{MPS}}$ → 19.3071, X22$_{\text{MPS}}$ → 500., X23$_{\text{MPS}}$ → 475.92, X24$_{\text{MPS}}$ → 24.08,
X25$_{\text{MPS}}$ → 0., X26$_{\text{MPS}}$ → 215., X28$_{\text{MPS}}$ → 0., X29$_{\text{MPS}}$ → 0., X30$_{\text{MPS}}$ → 0.,
X31$_{\text{MPS}}$ → 0., X32$_{\text{MPS}}$ → 0., X33$_{\text{MPS}}$ → 0., X34$_{\text{MPS}}$ → 0., X35$_{\text{MPS}}$ → 0.,
X36$_{\text{MPS}}$ → 339.943, X37$_{\text{MPS}}$ → 383.943, X38$_{\text{MPS}}$ → 0., X39$_{\text{MPS}}$ → 0.}}

Appendix

Introduction to *Mathematica*

1. Executing commands:

- To do a calculation with *Mathematica*, write the command into the notebook document (possibly with the help of a palette) and then execute it either by pressing the Enter key in the numeric keypad or by holding down the Shift key and then pressing the Return key.

2. Arithmetic:

- For addition, subtraction, division, and power, use +, −, /, and ^.
- For multiplication, usually the space key is used, but the ∗ key can also be used. For example, **`a b`** or **`a*b`** is a product but **`ab`** is a single variable.

3. Useful techniques:

- To give a name for a result, use =; for example, **`a = 17^2`**.
- To clear the value of a name, use **`=.`**; for example, **`a =.`**.
- To refer to the last result, use %; for example, **`% + 18^2`**.
- If an input is ended with a semicolon (**`a = 17^2;`**), the input is processed (after pressing, say, Enter) but the result is not shown in the notebook.
- Input and output labels of the form `In[` *n*`] :=` and `Out[` *n*`] =` can be turned off from *Mathematica* ▹ Preferences: go to Evaluation and uncheck "Show In/Out names".

4. Important conventions:

- All built-in names start with a capital letter.
- The argument of functions and commands are given within square brackets `[ ]`.
- Parentheses `( )` are only used for grouping terms in expressions.

5. Constants and mathematical functions:

- **`Pi`** (3.141...), **`E`** (2.718...), **`I`** ($\sqrt{-1}$), **`Infinity`**.
- **`Sqrt[z]`** or **`z^(1/2)`**, **`Exp[z]`** or **`E^z`**, **`Log[z]`** (the natural logarithm), **`Log10[z]`** (base-10 logarithm), **`Abs[z]`**, **`Sin[z]`**, **`ArcSin[z]`**, **`n!`**, **`Binomial[n, m]`**.

6. Lists:
   - A list is formed with curly braces { }; an example: **`v = {4, 7, 5}`**. A list is simply an ordered collection of elements. Lists can be nested, for example **`m = {{4, 7, 5}, {2, 6, 3}}`**.
   - Parts of lists (and of more general expressions) can be picked up with double square brackets **`[[ ]]`**. For example, **`m[[2]]`** gives **`{2, 6, 3}`** and **`m[[2, 1]]`** gives **`2`**.
7. Useful commands:
   - A decimal value can be obtained using **`N[expr]`**.
   - A decimal value to **`n`** digit precision can be obtained using **`N[expr, n]`**.
   - Numbers near to zero can be set to 0 with **`Chop[expr]`**.
   - An expression can be simplified with **`Simplify[expr]`**.
   - An expression can be expanded out with **`Expand[expr]`**.
   - All commands with a single argument can also be applied with **`//`**; for example, **`expr // N`** means **`N[expr]`**.
8. Replacements:
   - The syntax **`expr /. x → a`** is used to replace **`x`** with **`a`** in **`expr`**. Here, **`x → a`** is a transformation rule and /. is the replacement operator. The arrow → can be written by typing the two characters −> with no space in between; *Mathematica* transforms −> to a genuine arrow.
9. Mapping and threading:
   - With **`Map`** we can map the elements of a list with a function; that is, with **`Map`** we can calculate the value of a function at points given in a list. For example, **`Map[f[#] &, {a, b, c}]`** gives `{f[a], f[b], f[c]}` (a function like **`f[#] &`** is called a pure function). If **`f`** is a built-in function with one argument, the name of the function suffices. For example, if we want to calculate the 2-norms of the rows of a matrix **`m`**, we can write **`Map[Norm[#] &, m]`** but also simply **`Map[Norm, m]`**.
   - With **`Thread`** we can apply an operation to corresponding parts of two lists. For example, **`Thread[{x + y, x - y} == {2, 5}]`** gives `{x + y == 2, x - y == 5}`.
10. Functions and programs:
    - The syntax **`f[x_] := expr`** is used to define functions. For example, **`f[x_, y_] := x + Sin[y]`**.
    - In programs, we often use **`Module`** to define local variables or **`With`** to define local constants. The syntax is **`f[x_] := Module[`**{local variables}, body] (similarly for **`With`**).
11. Using saved notebooks:
    - When you open a saved notebook, *Mathematica* will not automatically process the inputs anew. So, if the notebook contains the definition **`a = 17^2`** and you also want to use this definition in the new *Mathematica* session, you have to process the input anew; simply put the cursor anywhere in the input and press Enter or Shift-Return.

An updated and expanded version of this chapter is available in the Sage documentation as a thematic tutorial on linear algebra.

91.1 Introduction

Sage is generally recognized as the leading comprehensive open source mathematics software system. Development began in 2005 by William Stein and progressed rapidly due to the incorporation of many mature open source packages for various areas of mathematics. The main web site for Sage is Free downloads of Sage, free public servers, and many other resources are located at the web site.

Sage is distributed with an open-source license (GPL version 3), which provides several advantages over commercial offerings.

- There is no cost to obtain or upgrade Sage. Collaborators and students have a platform that does not depend on institutional licenses and remains accessible in the future.
- *All* source code can be freely examined, modified, and redistributed. Algorithms can be traced and examined, bugs can be located, and improvements and bugfixes can be made and distributed freely. Often, bugs and improvements are made by experts in the field and frequent updates make these available rapidly.
- Every copy includes the web server software to run Sage as a multi-user server, so workgroups and educational institutions can provide computational services over the Internet at no additional cost.
- Many routines in Sage leverage highly specialized packages included in Sage that are written and vetted by experts. Many of these packages have been developed over decades and are reliable and fast.

Users may interact with Sage via a command-line interface or via a web interface known as the Sage Notebook. The Sage Notebook is a web application that runs in a web browser and serves as a front end for a Sage server, which may run on a remote computer or on the local computer. The online notebook is the easiest way to begin working with Sage since it works in any modern web browser (including on mobile devices) and requires no extra installation. A free public Sage server is accessible from `http://sagemath.org`.

Sage understands mathematical objects like rings, fields, vector spaces, matrices over different fields, etc. Each vector and matrix knows the ring in which its entries live, such as integers, rationals, elements of a finite field, floating-point double-precision reals (or complexes), high-precision reals (or complexes), or more exotic objects such as multivariate polynomials or algebraic numbers. Different routines or libraries will be transparently used depending on the type of entries. Sage includes many linear algebra libraries which it uses to do computations, including LAPACK, LinBox, IML, M4RI, etc. Support for floating-point double-precision matrices is provided by the included SciPy and NumPy scientific computation packages, which ultimately rely on LAPACK and other standard packages.

Extensive help and additional resources can be obtained freely through the Sage web site at `http://sagemath.org`. Context-sensitive help can be easily obtained by evaluating a function or method name followed by a question mark. Functions and methods can be discovered using tab-completion (see below).

In this chapter, example lines that start with `sage:` are input lines, and everything on an input line following the `sage:` prompt should be typed into Sage. Evaluate input by pressing the Enter key (in the command line) or by clicking evaluate or pressing Shift-Enter (in the notebook). In the examples below, the Sage output immediately follows the input on separate lines without `sage:` prompts. An ellipsis `...` indicates output that has been deleted for brevity.

91.2 Working with Sage

Facts:

1. You can use Sage in a web browser by accessing the Sage Notebook, which can be served from your own computer or a remote computer (such as a public server accessible from `http://sagemath.org`). You can also run Sage in command-line mode on your own computer (`exit` or `quit` will stop Sage). If you are running Sage in command-line mode, you can start the online notebook server for only your own computer by typing `notebook()` at the `sage:` prompt; stop the notebook with Control-C. You can also download an Apple OS X Sage application that lets you start a local Sage notebook or command-line environment by double-clicking.
2. Users use the general-purpose, popular, and easy-to-learn Python programming language to interact with Sage. Python is used in many scientific and other disciplines, so learning Python has many applications beyond Sage. Sage also includes many libraries that are compiled C, C++, Fortran, or other languages, but the "glue" tying everything together, as well as a substantial mathematical library, is also implemented in Python.
3. Mathematical objects in Sage belong to "parents," an idea pioneered by the Magma computer algebra system. Allowable operations, available methods, implemented algorithms, and documentation are all sensitive to an object's parent.
4. What Sage prints (the text representation), and what Sage knows, are two different things, and often what is printed is not the full story. The `parent()` method is helpful in understanding an object.

5. Much of Sage is object-oriented, and vectors, matrices, and vector spaces are considered objects. If an object is assigned a name, then typing the name, then a period, and then a method name followed by parentheses will have Sage call the method to return a result. For example, if `A` is a matrix, then `A.det()` will calculate the determinant of `A` using the `det()` method. Typing the name, appending a period, and then pressing the `Tab` key will bring up a full list of the methods available for that object (e.g., if `A` is a matrix, try `A.<tab>`, or `A.a<tab>` to see all methods beginning with an "a"). Many computations are also available as top-level commands (you can use either `det(A)` or `A.det()` to calculate the determinant). Appending a question mark to a command or method name, such as `A.det?`, and evaluating gives the documentation for the function or method (and the method documentation is context sensitive, depending on the object). Appending two question marks will display the source code for the command, method, or object.

   Documentation of commands and methods contains short informative examples that are tested for accuracy. The possible methods and documentation for vectors and matrices may greatly depend on the types of entries it contains. A quick way to learn about the capabilities of Sage is to build the revelant object (for example, a matrix) and explore methods and their documentation using tab completion and question marks.
6. Sage implements a variety of rings and fields that can be used as entries of vectors or matrices. Some common fields are listed below. The `RDF`, `CDF`, `RR`, and `CC` fields have 53-bit precision (see Section 91.11). `RealField`, `ComplexField`, `RealIntervalField`, and `ComplexIntervalField` support arbitrary precision. All other fields listed are exact with no round-off error.

Field	Name	Notes
Symbolic	`SR`	Used with symbolic variables
Rationals	`QQ`	
Mod p	`Integers(p)` or `GF(p)`	p prime, $p = 2$ highly optimized
Finite Field	`GF(p^n, ’a’)`	p prime
Q[sqrt(d)]	`QuadraticField(d, ’a’)`	Generator `a`
Cyclotomic Fields	`CyclotomicField(n)`	Rationals with nth roots of unity
Number Fields	`NumberField(poly, ’a’)`	Irreducible `poly`, generator `a`
Algebraic Numbers	`QQbar`	Algebraic closure of `QQ`
Algebraic Reals	`AA`	Real numbers in `QQbar`
Machine Reals	`RDF`	Best for numerical linear algebra
Machine Complexes	`CDF`	Best for numerical linear algebra
Reals	`RealField(prec)`	`prec` = precison in bits
Complexes	`ComplexField(prec)`	`prec` = precison in bits
Reals	`RR`	Same as `RealField(53)`
Complexes	`CC`	Same as `ComplexField(53)`
Real Interval	`RealIntervalField(prec)`	`prec` = precision in bits
Complex Interval	`ComplexIntervalField(prec)`	`prec` = precision in bits

7. Create symbolic variables with `var()`. Note that `x` is predefined at startup to be a symbolic variable (you will need to create any other symbolic variables).
8. Indices of vectors, matrix rows, matrix columns, lists, and tuples all begin at 0. For example, the third row of a matrix is accessed with the index 2. While perhaps uncomfortable at first, this makes programming easier, and makes vectors and matrices consistent with similar Python constructs.
9. Large matrices (at least 20 rows or 50 columns) do not print all their entries by default. To print the entries, do `print A.str()`. You can adjust the cutoff for this behavior using `sage.matrix.matrix0.set_max_rows` and `sage.matrix.matrix0.set_max_cols`.

10. We can save vectors and matrices (and most objects in Sage) to a file with the `save()` method. Given a filename, the `load()` function returns the saved object. This lets us save the results of a computation and then resume it later or on another computer.
11. Vectors and matrices may be immutable, which means that they cannot be changed. For example, the reduced row-echelon form of a matrix is typically cached (and hence made immutable) so that another computation for the same matrix will not need to repeat the reduction to echelon form. We can make a matrix `A` immutable using `A.set_immutable()`. We can use the `copy()` function to make a mutable copy.
12. Place comments in your code by prefixing each comment with `#`. Comments extend from `#` to the end of the line.
13. Place several commands on a single line by separating them with a semi-colon: `a = 4; a + 7`. Several quantities can be output in one tuple by creating a single command with values separated by commas: `2+3, 8-7`.
14. In the notebook, only the value of the last expression is printed. An assignment of a value to a variable will not produce any output. A common idiom for assigning `v` to the result of a command and then displaying `v` is `v = some_command(); v`.
15. Lists in Sage are delimited by brackets `[,]`. Entries may be added, removed, and sorted. Duplicates are allowed. Sage also has a `set` data type, for which duplicates are removed, and determining membership is very fast. Tuples are very similar to lists, but are immutable, and are delimited by parentheses `(,)`. Be careful not to confuse tuples with vectors, since vectors also print using parentheses. Lists, tuples, and sets are part of the Python language. The official Python tutorial in the Python documentation has an excellent discussion of lists, tuples, and sets.
16. Python has a very convenient way to build lists using list comprehensions, which is similar to set-builder notation.
17. `lambda` is a reserved word in Python, so it cannot be used as a variable name! `lambda` is used to create short unnamed functions (i.e., "anonymous" functions).
18. By default, `I` and `i` are both predefined as the complex number $i = \sqrt{-1}$.
19. Occasionally, you may want to overwrite a variable that Sage predefines with your own value, like using `i` as an index or setting `I` to be an identity matrix. To access Sage's predefined variable, prepend `sage.all.` to the variable (e.g., `sage.all.I` is the square root of -1, even if you have redefined `I`). Use the `reset()` function to reset variables to Sage defaults (e.g., `reset('I')` resets `I` to $\sqrt{-1}$, and `reset()` will reset all variables to Sage's default values).

Examples:

1. The parent of an object helps distinguish between objects that may print the same.

```
sage: 5, parent(5) # this "5" is an integer
(5, Integer Ring)
sage: 5/1, parent(5/1) # this "5" is a rational
(5, Rational Field)
```

2. Mutable and immutable matrices:

```
sage: A = matrix(QQ, 3, 4, range(12)); A.is_mutable()  # can change A
True
sage: B = A.rref(); B.is_immutable()  # can't change B
True
sage: C = copy(B); C.is_mutable()  # can change C
True
sage: C[0,0] = 100  # change the upper-left element of C
```

3. List comprehensions provide an easy way to map functions or filter.

```
sage: v = vector([-2, 3, 4, -6, 5])
sage: [i^2 for i in v], [i^2 for i in v if i > 0]
([4, 9, 16, 36, 25], [9, 16, 25])
```

91.3 Vectors

Commands:

1. **Constructors**: Sage has a number of ways to construct vectors.
   - (a) Construct vectors over a specific ring with `vector(ring, entries)`.
   - (b) The ring is optional; if not provided, Sage will infer the ring from the entries. The `base_ring()` method gives the ring of the entries. We can construct a new vector over a different base ring by using the `change_ring()` method.
   - (c) Create vector-valued symbolic functions with `f(inputs) = [outputs]` syntax.
   - (d) The `zero_vector()` and `random_vector()` commands construct zero and random vectors. The options to `random_vector()` depend on the ring; see the `random_element()` method documentation for the ring for details (for example, `QQ.random_element?`).
2. **Properties**
   - (a) In Sage, vectors do not have a column or row orientation. Instead, Sage interprets the vector as either a row or column as the situation demands. In order to explicitly get a row or column vector (i.e., a single-row or single-column matrix), use the `row()` or `column()` methods.
   - (b) Use square brackets to access an element of the vector. Remember that the indices start at zero.
   - (c) To get the number of elements in a vector, use the `len()` command.
   - (d) The `norm()` method gives the vector 2-norm. We can specify a p to compute a p-norm for any $p \geq 1$ (including `Infinity`).
   - (e) The `n()` method gives a numerical approximation. We can specify a precision or number of digits.
3. **Manipulations**
   - (a) Linear combinations use standard notation, like `2*u + 3*v`.
   - (b) The default product `u*v` of two vectors is the dot product. We can also use the `dot_product()` method. The `hermitian_inner_product()` method conjugates the first vector before taking the dot product. There are also `outer_product()` and `cross_product()` methods (cross product works for 3- and 7-dimensional vectors).
   - (c) The `apply_map()` method will apply a function to each element of the vector. Equivalently, you could also explicitly construct a new vector using a list comprehension.

Examples:

1. Construct vectors:

   ```
   sage: v = vector(QQ, [1,2,3]); v
   (1, 2, 3)
   sage: v.change_ring(RDF)
   (1.0, 2.0, 3.0)
   sage: v.apply_map(lambda x: x^2)  # also f(x) = x^2; v.apply_map(f)
   (1, 4, 9)
   sage: random_vector(QQ, 10, num_bound=15, den_bound=5)  # random
   (-2, -5/2, 15/4, 1, -11/4, 1, -13/4, 10, -3, 1)

   sage: x,y = var(’x,y’); vector(SR, [x, y, x*sin(y)])
   (x, y, x*sin(y))
   sage: f(x,y) = [x, y, x*sin(y)]; f  # vector-valued function
   (x, y) |--> (x, y, x*sin(y))
   sage: f(1,2)
   (1, 2, sin(2))
   ```

2. Properties of a vector. `w.n(20)` gives **w** with 20 bits of precision; use `w.n(digits=20)` for 20 digits.

   ```
   sage: v = vector(QQ, [21,-3,-1,2]); v[0], len(v)
   (21, 4)
   sage: v.norm(), v.norm(1), v.norm(2), v.norm(5), v.norm(Infinity), v.norm(x)
   (sqrt(455), 27, sqrt(455), 4084377^(1/5), 21, (2^x + 3^x + 21^x + 1)^(1/x))
   sage: w = vector(SR, [pi, e, 3/7]); w.n(), w.n(digits=2)
   ((3.14159265358979, 2.71828182845905, 0.428571428571429), (3.1, 2.7, 0.43))
   ```

3. Vector arithmetic:

   ```
   sage: u = vector(QQ, [1, 2, 3]); v = vector(QQ, [4, 3, -1])
   sage: 2*u + 3*v, u.cross_product(v)
   ((14, 13, 3), (-11, 13, -5))
   sage: u*v, u.dot_product(v), vector(SR, [4,2+I,3]).hermitian_inner_product(u)
   (7, 7, -2*I + 17)
   sage: u.outer_product(v)  # same as: u.column() * v.row()
   [ 4  3 -1]
   [ 8  6 -2]
   [12  9 -3]
   ```

91.4 Matrices

Commands:

1. **Constructors**
   (a) The `matrix(ring, entries)` command constructs a matrix over a specific ring of a specific size. The entries can be given as a list of rows or row vectors. If the dimensions of the matrix are supplied before the entries parameter, then the entries parameter can just be a list of entries or a function mapping indices (zero-based) to entry values. A base ring will be inferred if not specified.

(b) The `column_matrix()` command takes a list of columns instead of a list of rows.

(c) A variety of functions construct special types of matrices.

Description	Example
Diagonal matrix	`diagonal_matrix(QQ, [1,2,3])`
Identity matrix	`identity_matrix(3)`
Zero matrix	`zero_matrix(3,4)`
All-ones matrix	`ones_matrix(3,4)`
Elementary matrix	`elementary_matrix(QQ, 4, row1=3, scale=-2)`
Random matrix	`random_matrix(RDF, 3,4)`
Hadamard matrix	`hadamard_matrix(4)`
Polynomial companion matrix	`companion_matrix((x^2-2*x+1).polynomial(QQ))`

The `zero_matrix()`, `ones_matrix()`, and `random_matrix()` functions also can take a single number to construct a square matrix. For more options to give to the `random_matrix()` function, see the `random_element()` method for the ring of entries (e.g., `RDF.random_element?`). The `random_matrix()` constructor also takes an `algorithm` keyword that can be used to create small example matrices with integer entries that are "nice" to work with. Values of this keyword can be `echelonizable`, `unimodular`, `subspaces`, or `diagonalizable` and will create matrices (respectively) with a "nice" echelon form; with determinant one; with simultaneously "nice" bases for the row space, column space, right kernel, and left kernel; or similar to a diagonal matrix.

(d) The included SciPy linear algebra package has a number of matrices as well, including the above and Hankel, Leslie, Pascal, Toeplitz matrices, and more.

(e) You can construct the space of all matrices `M` with a given base ring and size and use this space to construct matrices. There are also other methods of matrix spaces; see the Sage reference manual.

2. **Block Matrix Constructors**

(a) The `block_matrix()` and `block_diagonal_matrix()` commands create block matrices (see Example 2 next). Blocks may be rectangular, integer arguments are converted to blocks with diagonal entries equal to the integer, and the result carries the natural subdivisions by default. See the `block_matrix()` documentation for many more features.

(b) The matrix methods `block_sum()` (for block diagonal results), `augment()` (concatenate horizontally), and `stack()` (concatenate vertically) provide alternative ways to combine two matrices or a matrix and a vector.

(c) Sage matrices can be subdivided into blocks (i.e., partitioned into submatrices). Blocks are created with the `subdivide()` method (specify row and column indices before each subdivision point), while the `subdivisions()` method returns this subdivision. The `subdivision()` method retrieves a specified block, and the `subdivision_entry()` returns a specified entry of a specified block. If arithmetic is done between matrices with compatible subdivisions, the result also has the natural subdivision. See Example 2 next.

3. **Properties**

(a) The `I`, `C`, `T`, and `H` attributes give the inverse, conjugate, transpose, and conjugate transpose (Hermitian transpose) of the matrix. Do not use parentheses when using these (e.g., `A.I`). The `I`, `C`, `T`, and `H` attributes are shortcuts for the `inverse()`, `conjugate()`, `transpose()`, and `conjugate_transpose()` methods, respectively. The inverse of a matrix is also `A^-1` and `~A`.

(b) Matrices have a number of methods for standard computations (e.g., `A.det()`).

Method	Description
`density()`	Density of nonzero entries
`det()`	Determinant
`minors(k)`	List of all k by k minors, in lexicographic order
`ncols()`	Number of columns
`norm(p)`	Norm, `p` can be 1, 2, `Infinity`, or `'frob'` (Frobenius)
`nrows()`	Number of rows
`permanent()`	Permanent
`permanental_minor(k)`	Sum of permanents of all possible k by k submatrices
`rank()`	Rank
`trace()`	Trace

(c) There are also several other commands to return various matrices.

Description	Example
Adjoint	`A.adjoint()`
Antitranspose	`A.antitranspose()`
Commutator $(AB - BA)$	`A.commutator(B)`
Matrix exponential, $\sum_{k=0}^{\infty} \frac{A^k}{k!}$	`A.exp()` (Use `RDF` or `CDF` matrices)
Elements satisfying given condition	`A.find(lambda x: x<0)`
Numerical approximation	`A.n()`, `A.n(digits=4)`, `A.n(10)` (10 bits)

The `find()` method makes a matrix with ones where the original matrix entries satisfied the given condition and zeros elsewhere. The `indices=True` option returns instead a dictionary of indices and elements satisfying the condition.

(d) The `A.iterates(v, n, rows=...)` method takes a vector $\mathbf{v}$ and a number n, and returns the vectors $\mathbf{v}, A\mathbf{v}, A^2\mathbf{v}, \ldots, A^{n-1}\mathbf{v}$ as rows (if `rows=True`, which is default) or columns (if `rows=False`) of a matrix.

(e) The `charpoly()` and `minpoly()` methods return the characteristic and minimal polynomial, respectively. Each function optionally takes a variable name.

(f) The following methods give the indices of various nonzero elements of a matrix, row, or column (remember that indices start at zero): `nonzero_positions()`, `nonzero_positions_in_row()`, and `nonzero_positions_in_column()`.

(g) `A.column_space()`, `A.row_space()`, `A.right_kernel`, and `A.left_kernel()` construct the corresponding vector spaces. *Warning*: Default versions of these commands are generally the left versions, so `A.kernel()` is the left kernel and `A.image()` is the row space, consistent with the $\mathbf{x} \mapsto \mathbf{x}A$ transformation, where the vector is on the left in the product.

(h) Matrices have numerous predicates that start with `is_`, for example, `A.is_invertible()`. The `is_similar()` method can optionally return a transformation matrix.

Method	True if
`is_bistochastic()`	Each row and column sums to 1
`is_dense()`	Matrix is stored in a dense data structure
`is_diagonalizable()`	Matrix is similar to a diagonal matrix
`is_hermitian()`	Matrix is equal to its conjugate transpose
`is_idempotent()`	Matrix is equal to its square
`is_immutable()`	Matrix entries cannot be changed
`is_invertible()`	Matrix is invertible over its base ring
`is_mutable()`	Matrix entries can be changed
`is_one()`	Matrix is identity matrix
`is_scalar()`	Matrix is a multiple of the identity matrix
`is_similar()`	Matrix is similar to another given matrix
`is_singular()`	Matrix is not invertible
`is_skew_symmetric()`	Matrix is equal to its negative transpose
`is_sparse()`	Matrix is stored in a sparse data structure
`is_square()`	Matrix has the same number of rows and columns
`is_symmetric()`	Matrix is equal to its transpose
`is_unitary()`	Columns form an orthonormal basis
`is_zero()`	Every entry is zero

4. **General manipulations**
   (a) Arithmetic with matrices uses standard notation, like `2*A - A*B + A^3 - A^-1`.

   (b) Recall that Sage vectors do not have an implicit row or column orientation. If A is a matrix and $\mathbf{v}$ is a vector, then `A*v` views $\mathbf{v}$ as a column vector and `v*A` views $\mathbf{v}$ as a row vector. In order to get a specific orientation for $\mathbf{v}$, convert it to a single-row or single-column matrix using `v.row()` or `v.column()`.

   (c) `A.elementwise_product(B)` computes the Hadamard product of A and B, while `A.tensor_product(B)` computes the tensor product. Subdivisions are automatically added for tensor products; do `A.tensor_product(B, subdivide=False)` to not have the result subdivided. `A.trace_of_product(B)` method computes the trace of AB without actually computing AB.

   (d) `A.apply_map(function)` will return a new matrix resulting from applying the function to each element of A, like `f(x) = x^2; A.apply_map(f)` or simply `A.apply_map(lambda x: x^2)`.

5. **RREF**: There are several ways to compute reduced row-echelon form (e.g., `A.rref()`).

Method	Description
`rref()`	Calculate RREF (over fraction field)
`echelon_form()`	Calculate RREF (over base ring)
`echelonize()`	Modify the matrix to echelon form (over base ring)
`extended_echelon_form()`	Augment with identity matrix before reducing

   (a) There are a number of commands to perform elementary operations on a matrix. Each command also has a variant that returns a new matrix instead of modifying the matrix—these variants have the same name, but in past tense and prefixed by `with_`. For example, `A.rescale_row(0,2)` rescales row 0 of A by a factor of 2, while `A.with_rescaled_row(0,2)` does not modify A, but returns a new matrix that is equal to A, except row 0 is scaled by 2. Remember again that row and column indexing starts at zero.

Row operation	Example
$C_2 \leftarrow C_2 - 4C_1$	`A.add_multiple_of_column(2,1,-4)`
$R_2 \leftarrow R_2 - 4R_1$	`A.add_multiple_of_row(2,1,-4)`
$C_0 \leftarrow 3C_0$	`A.rescale_col(0, 3)`
$R_0 \leftarrow 3R_0$	`A.rescale_row(0, 3)`
$C_0 \leftarrow 3C_2$	`A.set_col_to_multiple_of_col(0,2,3)`
$R_0 \leftarrow 3R_2$	`A.set_row_to_multiple_of_col(0,2,3)`
$C_0 \leftrightarrow C_2$	`A.swap_columns(0,2)`
$R_0 \leftrightarrow R_2$	`A.swap_rows(0,2)`

(b) The `pivots()` method returns the indices of the pivot columns and `nonpivots()` returns the indices of the nonpivot columns. The `pivot_rows()` method returns the indices of a topmost subset of the rows that span the row space and are linearly independent.

6. **Solving systems**: Sage has specialized methods for solving systems of linear equations over a variety of rings, which can be significantly more efficient and stable than inverting a matrix. To solve a system of linear equations of the form $A\mathbf{x} = \mathbf{b}$ or $AX = B$ (X and B matrices), use the matrix `solve_right()` method or the synonymous backslash syntax `A \ b`. The `solve_left()` method solves equations of the form $\mathbf{x}A = \mathbf{b}$ or $XA = B$.
7. **Left vs. Right**: Sage can do many calculations dealing with right ($A\mathbf{x}$) or left ($\mathbf{x}A$) matrix-vector products. The right or left tells which side the vector is on. Typically, "right" computations return vectors of interest as columns, while "left" computations return vectors of interest as rows. *Warning*: Sage typically defaults to left versions of commands (e.g., `A.kernel()` is `A.left_kernel()`). Use the right or left versions of commands below to be explicit.

Right: $A\mathbf{x} = \mathbf{b}$	Left: $\mathbf{x}A = \mathbf{b}$
`right_eigenmatrix()`	`left_eigenmatrix()`
`right_eigenspaces()`	`left_eigenspaces()`
`right_eigenvectors()`	`left_eigenvectors()`
`right_kernel()`	`left_kernel()`
`right_nullity()`	`left_nullity()`
`solve_right()`	`solve_left()`

8. **Indexing**: Sage supports very flexible ways of getting and setting elements of matrices. `A[i,j]` returns the entry in row i and column j (indices start at zero). The following table gives some general patterns for the index syntax, which is similar to NumPy or MATLAB syntax. If an index is negative, it counts backward from the last index (e.g., `A[-1,:]` is the last row), and if a step size is negative, it indicates a count down (e.g., `A[::-1,:]` gives a new matrix with the rows reversed). See the Sage reference manual on matrix indexing, `http://www.sagemath.org/doc/reference/sage/matrix/docs.html#indexing`.

Index	Description
`i`	Index i
`:`	All indices
`i:`	Indices from i to the end
`:j`	Indices up to, but not including, j
`i:j`	Indices from i up to, but not including, j
`i:j:s`	Every sth index from i up to, but not including, j
negative	Count backward from the last index
list	Explicit list of indices, possibly with repeats and reorderings

In the methods below, row and column index lists can contain repeated or reordered indices. The row and column methods at the end of the table below return vectors or lists of vectors, while the equivalent index notation returns submatrices. The second table below indicates how to modify submatrices using methods or indexing notation.

Method	Equivalent indexing
`A.diagonal()`	None
`A.matrix_from_columns([2,3])`	`A[:,[2,3]]`
`A.matrix_from_rows([2,3])`	`A[[2,3],:]`
`A.matrix_from_rows_and_columns([2,3],[3,4])`	`A[[2,3],[3,4]]`
`A.submatrix(i,j,nrows,ncols)`	`A[i:i+nrows, j:j+ncols]`
`A.column(i)`	`A[:,i]`
`A.columns([2,3])`	`A[:[2,3]]`
`A.row(i)`	`A[i,:]`
`A.rows([2,3])`	`A[[2,3],:]`

Method	Equivalent indexing
`A.set_block(i,j,B)`	`A[i:i+B.nrows(), j:j+B.ncols()]=B` (B a matrix)
`A.set_column(i, [2,1,3])`	`A[:,i]=vector([2,1,3])` or `A[:,i]=[[2],[1],[3]]`
`A.set_row(i, [2,1,3])`	`A[i,:]=vector([2,1,3])` or `A[i,:]=[[2,1,3]]`

9. **Sparse Matrices**: In order to handle large sparse matrices, Sage can store any matrix in a compressed way so that only the nonzero entries are stored. Create a sparse matrix by specifying `sparse=True` when the matrix is created. Matrices initialized from a Python dictionary default to sparse. The included SciPy Python package also has many resources for dealing with sparse matrices.
10. **Decompositions**: A variety of matrix decompositions are available in Sage, and many are available with algorithms for both exact and numerical matrices. Typically the return value is a tuple of matrices that can be used to reconstruct the matrix (except Jordan form, which requires explicitly asking for the transformation matrix). Some exact algorithms require the base ring of the matrix to have certain properties, such as containing square roots. In other cases, the matrix must have certain properties, such as having a characteristic polynomial that factors. These conditions are listed in the "Base ring must contain" column.

    Sage implements the algebraically closed field of algebraic numbers, `QQbar`, so some decompositions applied to matrices of rational numbers will automatically return matrices with entries from `QQbar` as necessary (e.g., Cholesky). On the other hand, `jordan_form` will simply fail if there are eigenvalues outside the base ring.

    Matrices over `RDF` and `CDF` use specialized numerical algorithms for the LU, QR, SVD, Schur, and Cholesky factorizations; see Section 91.11.

Name	Method	Base ring must contain
LU, Triangular	`LU()`	Fraction
QR, Gram-Schmidt	`QR()`	Fraction, square roots
SVD, Singular Value	`SVD()`	
Schur	`schur()`	
Cholesky, Square Root	`cholesky()`	Square roots
Jordan Form	`jordan_form()`	Eigenvalues
Rational Canonical Form (Invariant Factors)	`rational_form()`	Field
Smith Form	`smith_form()`	Principal ideal domain
Symplectic Form	`symplectic_form()`	Field
Subspace Decomposition	`decomposition()`	Factored characteristic polynomial

Examples:

1. Constructing matrices.

```
sage: matrix(QQ, [[1,0,1],[2,0,-1]])  # also matrix(QQ, 2, 3, [1,0,1,2,0,-1])
[ 1  0  1]
[ 2  0 -1]
sage: u = vector(QQ, [2,3]); v = vector(QQ, [5,0]); w = vector(QQ, [-1,2])
sage: column_matrix([u,v,w])
[ 2  5 -1]
[ 3  0  2]
sage: def vandermonde(R, v): return matrix(R, len(v), lambda i,j: v[i]^j)
sage: vandermonde(QQ, [2,3,4])
[ 1  2  4]
[ 1  3  9]
[ 1  4 16]
sage: def hilbert(R,n): return matrix(R, n, lambda i,j: 1/(i+j+1))
sage: hilbert(QQ, 3)
[  1 1/2 1/3]
[1/2 1/3 1/4]
[1/3 1/4 1/5]
```

2. Constructing block matrices.

```
sage: A = matrix(QQ, [[-1,1],[0,-1]]);  B = matrix(QQ, [[1,-1/2]])
sage: block_matrix(QQ, [[A,1],[0,B]])
[  -1    1|   1    0]
[   0   -1|   0    1]
[---------+---------]
[   0    0|   1 -1/2]
sage: block_diagonal_matrix([A,B], subdivide=False)
[  -1    1    0    0]
[   0   -1    0    0]
[   0    0    1 -1/2]
sage: A.augment(vector(QQ, [1,-1/2]), subdivide=True)
[  -1    1|   1]
[   0   -1|-1/2]
```

```
sage: A.stack(B)
[  -1    1]
[   0   -1]
[   1 -1/2]
```

We can subdivide an existing matrix to get a block matrix. Here, we subdivide just before row 2 and just before columns 1 and 3 (remember indices start at 0).

```
sage: C = matrix(QQ, 3, 5, range(15))
sage: C.subdivide([2],[1,3]); C
[ 0| 1  2| 3  4]
[ 5| 6  7| 8  9]
[--+-----+-----]
[10|11 12|13 14]
sage: C.subdivision(0,2) # block (0,2)
[3 4]
[8 9]
sage: C.subdivision_entry(0,2,0,1) # entry (0,1) in block (0,2)
4
sage: C * C.transpose() # arithmetic preserves block structure if possible
[ 30  80|130]
[ 80 255|430]
[-------+---]
[130 430|730]
```

3. Properties of a matrix.

```
sage: A = matrix(QQ, 2, [0,-1,2,-2]); A, A.I, A.T, A.find(lambda x: x<0)
(
[ 0 -1]  [ -1 1/2]  [ 0  2]  [0 1]
[ 2 -2], [ -1   0], [-1 -2], [0 1]
)
sage: A.find(lambda x: x<0, indices=True)
{(0, 1): -1, (1, 1): -2}
sage: A.change_ring(RDF).exp() # use RDF for numeric calculations
[    0.508325986 -0.309559875653]
[ 0.619119751306 -0.110793765307]
sage: A.norm(), A.norm(1), A.norm(Infinity), A.norm('frob')
(2.92080962648, 3.0, 4.0, 3.0)
```

```
sage: A = diagonal_matrix([2,2,5])
sage: A.charpoly(), A.minpoly()
(x^3 - 9*x^2 + 24*x - 20, x^2 - 7*x + 10)
sage: A.minors(2)
[4, 0, 0, 0, 10, 0, 0, 0, 10]
sage: A.det(), A.rank(), A.trace(), A.permanent(), A.permanental_minor(2)
(20, 3, 9, 20, 24)
```

4. Like many computer algebra systems, row-reducing a symbolic matrix using the `rref()` method assumes that we are working over a field (i.e., that if `c` is any nonzero element of the base ring, then `1/c` is also in the base ring). Since Sage can also work with matrices over general rings (which may not be fields), we can ask Sage to do operations without assuming that we can divide. For example, if a matrix has entries in a polynomial ring, we can ask for the `echelon_form()` of the matrix, which only uses operations in the polynomial ring (e.g.,

Sage will not divide except by constants). We can use the `matrix_over_field()` method to get a copy of a matrix over the fraction field of its base ring.

```
sage: R.<c1,c2,c3> = QQ[] # construct a polynomial ring with 3 variables
sage: A = matrix([[1,1,2,c1], [1,0,1,c2], [2,1,3,c3]]); A
[ 1  1  2 c1]
[ 1  0  1 c2]
[ 2  1  3 c3]
sage: A.rref() # works over fraction field of R, so 1/c1 exists, etc.
[1 0 1 0]
[0 1 1 0]
[0 0 0 1]
sage: A.echelon_form() # uses only operations in the polynomial ring R
[           1            0            1           c2]
[           0            1            1      c1 - c2]
[           0            0            0 -c1 - c2 + c3]
sage: B = A.matrix_over_field(); B.base_ring()
Fraction Field of Multivariate Polynomial Ring in c1, c2, c3 over Rational Field
sage: B.echelon_form() == A.rref()
True
```

5. We can easily get pivot columns.

```
sage: A = matrix(QQ, [[1,2,3,4],[2,4,6,8],[3,5,4,3]]); A.rref()
[  1   0  -7 -14]
[  0   1   5   9]
[  0   0   0   0]
sage: A.pivots(), A.nonpivots(), A.pivot_rows()
((0, 1), (2, 3), (0, 2))
sage: A[:,A.pivots()]  # get the pivot columns
[1 2]
[2 4]
[3 5]
sage: A[A.pivot_rows(),:]  # get the pivot rows
[1 2 3 4]
[3 5 4 3]
```

6. The `extended_echelon_form()` method first augments an m by n matrix with an m by m identity matrix before computing the rref. The result can also be subdivided by specifying `subdivide=True`. The four relations in the last two lines of this example are true in general.

```
sage: A = matrix(QQ, 3, 3, [2,3,4,-1,2,4,1,5,8])
sage: B = A.extended_echelon_form(subdivide=True); B
[   1    0 -4/7|   0 -5/7  2/7]
[   0    1 12/7|   0  1/7  1/7]
[--------------+--------------]
[   0    0    0|   1    1   -1]
sage: C = B.subdivision(0, 0); C  # C is upper-left submatrix
[   1    0 -4/7]
[   0    1 12/7]
sage: L = B.subdivision(1, 1); L  # L is lower-right submatrix
[ 1  1 -1]
sage: A.right_kernel() == C.right_kernel(), A.row_space() == C.row_space()
(True, True)
sage: A.column_space() == L.right_kernel(), A.left_kernel() == L.row_space()
(True, True)
```

7. We solve systems of equations using `solve_right` or backslash notation.

```
sage: A = matrix(QQ, 2, [1,2,3,4]); b = vector(QQ, [5,6])
sage: x = A.solve_right(b); x  # also x = A \ b
(-4, 9/2)
sage: A * x == b
True
sage: B = matrix(QQ, 2, 3, [5,1,0,6,0,1])
sage: X = A \ B; A * X == B  # also X = A.solve_right(B)
True
```

8. To be able to compute an exact QR decomposition, we need a field that contains square roots, so we create a matrix with entries from `QQbar`. Sage uses specialized numerical algorithms if the matrix is over `RDF`.

```
sage: A = matrix(QQbar, 3, 3, [0..8])  # [0..8] is [0, 1, 2, ..., 8]
sage: Q, R = A.QR(); A == Q*R and Q.is_unitary()  # True if both conditions are True
True
sage: B = matrix(RDF, 3, 3, [0..8])
sage: Q, R = B.QR(); (A - Q*R).norm() < 10^-10 and Q.is_unitary()
True
```

91.5 Eigenvalues and Eigenvectors

Sage will compute exact eigenvalues, eigenvectors, and eigenspaces for matrices with entries from exact rings, and will compute approximate eigenvalues and eigenvectors for matrices with floating-point entries. Both right and left variants of the eigenvector methods are available; we will only discuss the right variants.

Commands:

1. The `eigenvalues()` method computes the eigenvalues. If a matrix over `QQ` does not have rational eigenvalues, then the eigenvalues may be returned as algebraic numbers in `QQbar` (the algebraic completion of `QQ`) and printed as numeric approximations followed by question marks. The question mark indicates that the number is contained in the interval found by taking the last digit of the printed representation plus or minus one (e.g., `3.25?` represents an exact root in the interval $[3.24, 3.26]$). We emphasize that a `QQbar` element is an exact root of a polynomial and the printed approximation indicates an interval containing the value, and so may be slower to work with than computing the eigenvalues numerically using an `RDF` or `CDF` matrix.
2. The `eigenvectors_right()` method returns a list, each element of the following form: `(eigenvalue, list of eigenvectors, algebraic multiplicity)`.
   The `eigenspaces_right()` method returns a list, each element of the following form: `(eigenvalue, eigenspace)`, where the eigenspace is a Sage vector space.
3. The `eigenmatrix_right()` method of a matrix A returns two matrices D and P such that $AP = PD$. The eigenvalues are the diagonal of D and the corresponding eigenvectors are the columns of P. Columns of zeros in P indicate that the geometric multiplicity of the eigenvalue is not equal to the algebraic multiplicity.

Examples:

1. We calculate various eigenvalues, eigenvectors, and eigenspaces. Numerical matrices always claim eigenvalues have multiplicity one since numerical error can easily fool multiplicity calculations (see Section 91.11).

```
sage: entries = [-8,21,74,-48,24,-7,-78,72,-12,6,44,-36,-4,-3,2,-4]
sage: A = matrix(QQ, 4, 4, entries); A.eigenvalues()
[5, 4, 8, 8]
sage: A.eigenvectors_right()
[(5, [ (1, -5/7, 2/7, -1/7) ], 1),
 (4, [ (1, -3/2, 3/4, 1/4) ], 1),
 (8, [ (1, 0, 0, -1/3), (0, 1, -1/2, -1/3) ], 2)]
sage: A.eigenspaces_right()
[
(5, Vector space of degree 4 and dimension 1 over Rational Field ...),
(4, Vector space of degree 4 and dimension 1 over Rational Field ...),
(8, Vector space of degree 4 and dimension 2 over Rational Field ...)
]
```

2. The `eigenmatrix_right()` method provides a very easy way to get corresponding lists of eigenvalues and eigenvectors using the `diagonal()` and `columns()` methods of matrices.

```
sage: entries = [-8,21,74,-48,24,-7,-78,72,-12,6,44,-36,-4,-3,2,-4]
sage: A = matrix(QQ, 4, 4, entries)
sage: D, P = A.eigenmatrix_right(); D, P, A * P == P * D
(
[5 0 0 0]  [   1    1    1    0]
[0 4 0 0]  [-5/7 -3/2    0    1]
[0 0 8 0]  [ 2/7  3/4    0 -1/2]
[0 0 0 8], [-1/7  1/4 -1/3 -1/3], True
)
sage: evals = D.diagonal(); evecs = P.columns()
sage: A*evecs[0] == evals[0] * evecs[0]  # check first eigenvalue/eigenvector
True
```

3. For matrices with rational entries, we can optionally ask that eigenspaces be reported just once per irreducible factor of the characteristic polynomial since the eigenspaces for each irreducible factor are related in a natural way.

```
sage: A = matrix(QQ, 3, 3, [-7, 2, -22, 10, -3, 33, 3, -1, 10]); A.charpoly()
x^3 + 1
sage: A.eigenspaces_right(format='galois')
[
(-1, Vector space of degree 3 and dimension 1 over Rational Field ...),
(a1, Vector space of degree 3 and dimension 1 over
Number Field in a1 with defining polynomial x^2 - x + 1
User basis matrix:
[         1 1/2*a1 - 2       -1/2])
]
```

4. Even if Sage does not directly compute eigenvalues for matrices over some exotic ring, other tools may provide information you desire. For example, the `fcp()` method, which returns the factored characteristic polynomial, is often useful.

```
sage: F.<a> = FiniteField(3^2);
sage: A = matrix(F, 3, 3, [2*a, a, 2*a, 0, 2, a + 2, 2, a, 2*a]); A.fcp()
(x + a + 1) * (x^2 + a*x + 2)
sage: (A - (-a-1)*identity_matrix(3)).right_kernel()  # an eigenspace
Vector space of degree 3 and dimension 1 over Finite Field in a of size 3^2 ...
```

91.6 Vector Spaces

You can use `VectorSpace` objects to work directly with vector spaces.

Definitions:

1. The **basis matrix** of a vector space has the basis vectors of the vector space as its rows. By default, Sage will store and use a canonical **echelonized** basis for a vector space (i.e., the basis matrix will be a matrix in reduced row-echelon form). A **user basis** can also be explicitly used (see below for examples).
2. Vectors in a vector space V over a field F also live in some **ambient vector space** F^n. The degree of V is n. The **dimension** or **rank** of V is the size of the basis. A vector space is **full** if its degree equals its dimension.

Commands:

1. **Constructors**
   (a) The simplest way to create a vector space is to raise a field to a power (in general, raising a ring to a power will construct a free module). We can also use `VectorSpace` directly by providing a field and a dimension.
   (b) The `parent()` method of a vector returns the vector space containing the vector.
   (c) The `span()` command constructs the vector space spanned by a list of vectors.
   (d) Use the `subspace()` method to construct subspaces. The `subspace_with_basis()` method allows specifying a “user basis”.
2. **Properties**
   (a) `v in V` tests if the vector **v** is in the vector space V.
   (a) Check if two vector spaces V and W are equal with `V == W`. Check if V is a subspace of W using `V.is_subspace(W)`.
   (b) The basis (canonical basis) of a vector space is returned by the `basis()` (`echelonized_basis()`) method. The corresponding `basis_matrix()` and `echelonized_basis_matrix()` methods return matrices in which the basis vectors are the rows.
   (c) An element of a vector space can be expressed as a linear combination of the basis vectors (which are canonical by default). The scalars (i.e., coordinates) can be returned as a list (using the `coordinates()` method) or as a vector (using the `coordinate_vector()` method).
   (d) The `linear_dependence()` method takes a list of vectors and returns the coefficients of a nontrivial linear combination that equals zero. An empty sequence is returned if the vectors are linearly independent.
3. We can intersect two vector spaces (`U.intersection(V)`), add them (`U + V`), form their direct sum (`U.direct_sum(V)`), and take their quotient (`U / V`).

Examples:

1. Create a vector space, or more generally, a free module like `ZZ^3`.

```
sage: QQ^3
Vector space of dimension 3 over Rational Field
sage: VectorSpace(RDF, 3)
Vector space of dimension 3 over Real Double Field
```

2. Construct subspaces.

```
sage: u = vector(QQ, [1, 2, 3]); v = vector(QQ, [-3, 0, 3])
sage: S = span([u,v]); S  # basis echelonized, not (u,v)
Vector space of degree 3 and dimension 2 over Rational Field
Basis matrix:
[ 1  0 -1]
[ 0  1  2]
sage: T = S.subspace([u + v]); T  # the basis matrix is canonical
Vector space of degree 3 and dimension 1 over Rational Field
Basis matrix:
[ 1 -1 -3]
sage: U = S.subspace_with_basis([u + v]); U  # basis not echelonized
Vector space of degree 3 and dimension 1 over Rational Field
User basis matrix:
[-2 2 6]
```

3. Properties of vector spaces.

```
sage: u = vector(QQ, [1, 2, 3]); v = vector(QQ, [-1, 0, 1])
sage: W = span([u,v]); V = W.ambient_vector_space()
sage: W.degree(), W.dimension(), W.rank(), W.is_full(), V.is_full(), V == QQ^3
(3, 2, 2, False, True, True)
sage: S = span([v]); S.is_subspace(W), S == span([-v])
(True, True)
```

4. Vectors as elements of vector spaces. The `coordinates()` method below returns a Python list, while the `coordinate_vector()` method returns an actual vector.

```
sage: u = vector(QQ, [1, 2, 3]); v = vector(QQ, [-1, 0, 1]); x = 3*u - 7*v
sage: W = span([u,v]); W
Vector space of degree 3 and dimension 2 over Rational Field ...
sage: x in W, vector(QQ, [3, 7, 195]) in W
(True, False)
sage: W.coordinates(x), W.coordinate_vector(x)  # relative to the canonical basis
([10, 6], (10, 6))
sage: X = (QQ^3).subspace_with_basis([u, v]); X
Vector space of degree 3 and dimension 2 over Rational Field
User basis matrix:
[ 1  2  3]
[-1  0  1]
sage: X.coordinate_vector(x)  # relative to the user basis
(3, -7)
sage: X.linear_combination_of_basis([3, -7])
(10, 6, 2)
```

5. Vector space arithmetic.

```
sage: u = vector(QQ, [1,2,2]); v = vector(QQ, [-1,0,4])
sage: w = vector(QQ, [2,1,5])
sage: U = span([u + v, u - 3*v]); W = span([v + w, 5*v - 6*w])
sage: U.intersection(W)
Vector space of degree 3 and dimension 1 over Rational Field ...
sage: U + W
Vector space of degree 3 and dimension 3 over Rational Field ...
sage: U.direct_sum(W)
Vector space of degree 6 and dimension 4 over Rational Field ...
```

```
sage: u = vector(QQ, [1,2,2,5,3]); v = vector(QQ, [-1,0,4,3,1])
sage: U = span([u, v]); Q = (QQ^5).quotient(U); Q.dimension()
3
sage: phi = Q.quotient_map(); phi
Vector space morphism ...
sage: phi.kernel() == U
True
```

91.7 Linear Transformations

Commands:

1. If A is a matrix, `linear_transformation(A)` constructs the transformation $\mathbf{x} \mapsto \mathbf{x}A$. *Warning*: Notice again the preference for a product with the vector on the left. The domain and codomain are inferred from the base ring and matrix dimensions. Create the linear transformation $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$ by `linear_transformation(A, side='right')`, which just transposes A to create a left-sided version; the matrix stored and printed by the linear transformation is understood as the left version.
2. We can specify the rule for a linear transformation using a lambda function, a Python function defined with the `def` keyword, a symbolic function, or by a list of images for the elements of the domain's basis in place of the matrix A.
3. If T is a linear transformation and $\mathbf{v}$ is a vector, `T(v)` computes the image of $\mathbf{v}$.
4. `T.is_surjective()` and `T.is_injective()` query properties of a transformation T.
5. `T.image()`, `T.kernel()`, and `T.inverse_image(V)` construct related vector spaces.
6. Compose linear transformations by multiplying them together.
7. `T.restrict_domain()` and `T.restrict_codomain()` construct new transformations.

Examples:

1. Construct some linear transformations.

```
sage: A = matrix(QQ, 2, 3, range(6)); A
[0 1 2]
[3 4 5]
sage: T = linear_transformation(A); T
Vector space morphism represented by the matrix:
[0 1 2]
[3 4 5]
```

```
Domain: Vector space of dimension 2 over Rational Field
Codomain: Vector space of dimension 3 over Rational Field
sage: U = linear_transformation(A, side='right'); U
Vector space morphism represented by the matrix:
[0 3]
[1 4]
[2 5]
Domain: Vector space of dimension 3 over Rational Field
Codomain: Vector space of dimension 2 over Rational Field
sage: v = vector(QQ, [2,3,1]); U(v) == A * v
True
```

We can give the domain and codomain explicitly. The matrix is interpreted (and printed) as the representation relative to the bases of the domain and codomain.

```
sage: V = (QQ^2).subspace_with_basis([vector(QQ, [-1, 1])])
sage: W = (QQ^3).subspace_with_basis([vector(QQ, [0,1,0]), vector(QQ, [0,0,1])])
sage: A = matrix(QQ, [[2,5]]); T = linear_transformation(V, W, A); T
Vector space morphism represented by the matrix:
[2 5]
Domain: Vector space of degree 2 and dimension 1 over Rational Field ...
Codomain: Vector space of degree 3 and dimension 2 over Rational Field
User basis matrix:
[0 1 0]
[0 0 1]
sage: v = vector(QQ, [-4, 4]); T(v)
(0, 8, 20)
sage: V.coordinate_vector(v) * T.matrix() * W.basis_matrix()  # check
(0, 8, 20)
```

The third argument may be a function or list of images instead of a matrix.

```
sage: f = lambda x: vector(QQ, [2*x[0] + x[2], 5*x[1] - 6*x[2]])
sage: T = linear_transformation(QQ^3, QQ^2, f); T
Vector space morphism represented by the matrix:
[ 2  0]
[ 0  5]
[ 1 -6]
Domain: Vector space of dimension 3 over Rational Field
Codomain: Vector space of dimension 2 over Rational Field

sage: images = [vector(QQ, [1,2]), vector(QQ, [-2,4])]
sage: T = linear_transformation(QQ^2, QQ^2, images); T
Vector space morphism represented by the matrix:
[ 1  2]
[-2  4]
Domain: Vector space of dimension 2 over Rational Field
Codomain: Vector space of dimension 2 over Rational Field
```

2. Query properties of a linear transformation.

```
sage: A = matrix(QQ, 2, 3, range(6))
sage: T = linear_transformation(A)
sage: T.is_surjective(), T.is_injective(), T.image() == T(QQ^2)
(False, True, True)
sage: T.image()
Vector space of degree 3 and dimension 2 over Rational Field ...
sage: T.kernel()
```

```
Vector space of degree 2 and dimension 0 over Rational Field ...
sage: W = (QQ^3).subspace([vector(QQ, [2,3,4])]); T.inverse_image(W)
Vector space of degree 2 and dimension 1 over Rational Field ...
```

3. Composing and restricting linear transformations.

```
sage: A = matrix(QQ, [[2, 4, 2], [3, 6, 3]])
sage: T = linear_transformation(A); v = vector(QQ, [10, -15])
sage: T(v)
(-25, -50, -25)
sage: U = linear_transformation(diagonal_matrix([1, 1/2, 1/5]))
sage: (U * T)(v)
(-25, -25, -5)

sage: new_domain = (QQ^2).subspace([vector(QQ, [2,-3])])
sage: S = T.restrict_domain(new_domain); S
Vector space morphism represented by the matrix:
[-5/2   -5 -5/2]
Domain: Vector space of degree 2 and dimension 1 over Rational Field ...
Codomain: Vector space of dimension 3 over Rational Field
sage: S(vector(QQ, [10, -15]))
(-25, -50, -25)
```

Note that the matrix representations of the restrictions are with respect to the echelonized bases of the new subspaces.

91.8 Graphics

Sage has extensive capabilities for drawing 2D and 3D pictures and graphs. We demonstrate just a few of these capabilities here; see the Sage documentation for many more plotting capabilities.

Examples:

1. **Vectors**: `v.plot(start=u)` plots a vector **v** starting at **u**. Adding graphics objects superimposes them. Use `show()` to show a plot or use the `save()` method of a graphics object to save the plot to a file. We can save plots in a variety of formats (e.g., png, jpg, pdf, eps, svg, etc.). See Figure 91.1.

```
sage: u = vector(QQ, [1,2]); v = vector(QQ, [1,-1])
sage: p = v.plot() + u.plot(start=v) + (u+v).plot(linestyle='dashed')
sage: show(p) # show picture
sage: p.save('vectorplot.pdf') # save as a pdf file
```

2. **Matrices**: Sage plots matrices as rectangular arrays by mapping entry values to colors. A user-specified color map (rules for how values map to colors) can be given and a legend-like color bar can be added. In the following example (Figure 91.2a), we plot a Toeplitz matrix; you can clearly see the banded structure.

```
sage: from scipy.linalg import toeplitz
sage: A = matrix(QQ,toeplitz([cos(i) for i in range(10)]))
sage: A.plot(colorbar=True)
```

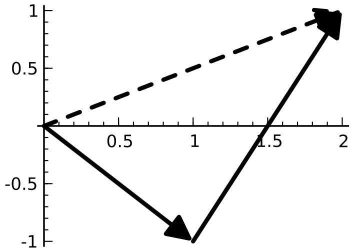

FIGURE 91.1: Vector plot.

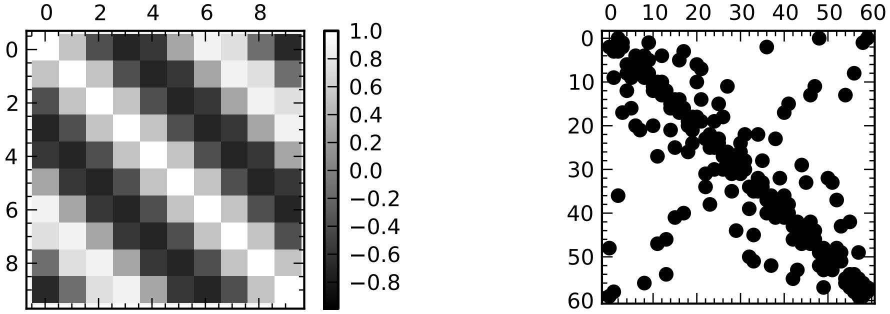

(a) (b)

FIGURE 91.2: Matrix plots.

Sparse matrices plot their nonzero values. Here we construct the adjacency matrix of the Buckyball graph and plot its structure (Figure 91.2b).

```
sage: A = graphs.BuckyBall().adjacency_matrix(sparse=True)
sage: A.plot()
```

91.9 Conversion to Other Forms

Examples:

1. Sage can convert a vector or matrix to a Python dictionary (`v.dict()`; returns indices and entries), a Python list (`v.list()`), or a NumPy array (`v.numpy()`).

```
sage: v = vector(QQ, [1,2,3]); v.dict()
{0: 1, 1: 2, 2: 3}
sage: A = matrix(QQ, [[1,2],[3,4]]); A.list()
[1, 2, 3, 4]
```

2. The LaTeX code for a vector or matrix can be generated using the `latex()` method:

```
sage: latex(vector(QQ, [1,2,3]))
\left(1,\,2,\,3\right)
sage: latex(matrix(QQ, 2, [1,2,3,4/7]))
\left(\begin{array}{rr}
1 & 2 \\
3 & \frac{4}{7}
\end{array}\right)
```

3. You can change LaTeX delimiters using the following functions: `latex.vector_delimiters()`, `latex.matrix_delimiters()`. If you use a delimiter that has a backslash, use two backslashes when specifying it, like `’\\langle’`, or prefix the string with `r`, like `r’\langle’`.

```
sage: latex.vector_delimiters(’\\langle’, r’\rangle’)
sage: latex(vector(QQ, [1,2,3/7]))
\left\langle1,\,2,\,\frac{3}{7}\right\rangle
```

91.10 General Rings

As mentioned earlier, every matrix and vector knows what ring in which its entries live, and this determines how a matrix prints, algorithms and libraries used to do the computations, methods available, etc. Sage also supports many more rings and fields than we have mentioned, including cyclotomic fields, number fields, and univariate and multivariate polynomial rings.

Examples:

1. The following matrix is invertible over the rationals, but not over the integers:

```
sage: A = matrix(QQ,2,[1,2,3,4])
sage: A.is_invertible(), A.change_ring(ZZ).is_invertible()
(True, False)
```

2. Sometimes matrices over certain fields support additional methods. For example, a symbolic matrix has a `subs()` method to substitute values in for variables:

```
sage: x,y,z = var(’x,y,z’); A = matrix(SR, [[x,x-3*y,z],[x*z,0,y-x]])
sage: A.subs(x=3, y=2)
[  3  -3   z]
[3*z   0  -1]
```

3. **Finite fields**: See Chapter 31 for more about matrices over finite fields.
   (a) Use the `FiniteField` command or its shorthand `GF` (“Galois Field”) to construct a finite field, specifying a name for the (multiplicative) generator if needed.

```
sage: FiniteField(37), GF(next_prime(10^5))
(Finite Field of size 37, Finite Field of size 100003)
sage: F = GF(3^2, ’a’); F.list()
[0, 2*a, a + 1, a + 2, 2, a, 2*a + 2, 2*a + 1, 1]
sage: F.<a> = GF(2^9); a^101
a^7 + a^6 + a^4 + a^3 + 1
```

   (b) Linear algebra can be done over these finite fields just like any other ring. Special implementations take advantage of different field characteristics to efficiently implement these. Linear algebra over `GF(2)` is particularly optimized.

```
sage: A = matrix(GF(5), 2, [1,2,3,14]); A.charpoly()
x^2 + 3
sage: A + A, A^-1, A^-1 * A
(
[2 4]  [3 1]  [1 0]
[1 3], [4 2], [0 1]
)
sage: B = matrix(GF(37), 3, [1,2,3,4,5,6,7,8,10]); b = vector([1,2,3])
sage: B * b, B \ b
((14, 32, 16), (12, 13, 0))
```

(c) Matrices over finite fields also support extra methods. Comparing a matrix to 1 compares it to the identity matrix.

```
sage: A = matrix(GF(37), 3, [1..8,10])
sage: A.multiplicative_order(), A^684 == 1
(684, True)
```

91.11 Numerical Linear Algebra

Facts:

1. The fields `RDF` and `CDF` are fast machine-level double-precision floating point reals and complexes (respectively). Many of the algorithms for matrices over `RDF` and `CDF` are provided by SciPy/NumPy and use industry-standard libraries like LAPACK.
2. The fields `RealField(prec)` and `ComplexField(prec)` provide reals and complexes to any fixed precision (`prec` is the number of bits used for the mantissa), e.g., `RealField(20)` has 20 bits of precision. In Sage, `RR` is `RealField(53)` and `CC` is `ComplexField(53)`. A floating point number is in `RR` or `CC` by default, so a matrix or vector with floating point entries is over `RR` or `CC` unless another ring is specified.
3. We emphasize that `RR` and `CC` are *not* exactly the same as `RDF` and `CDF` since `RR` and `CC` are not implemented with machine-level floating point numbers. The `RealField` and `ComplexField` fields (like `RR` and `CC`) are instead implemented with rigorous and portable semantics, and thus are usually slower. More importantly, algorithms for matrices over `RealField`, and `ComplexField` are not specialized for numerical work, so they may return misleading results because of numerical error.
4. Since the `v.n()` and `A.n()` numerical approximation methods return objects over `RR` or `CC`, if you are doing numerical computations, it is preferable to convert your objects to `RDF` or `CDF` using the `change_ring()` method, e.g., `v.change_ring(RDF)`.
5. `RDF` and `CDF` matrices used specialized algorithms for computing eigenvalues, eigenvectors, and popular matrix decompositions (see the relevant sections of Section 91.4 for specific methods). Eigenvectors (and eigenspaces) are reported with multiplicity one, for consistency with the format of results for exact matrices.
6. `RDF` and `CDF` matrices use specialized algorithms to compute properties like the condition number of a matrix (`A.condition()`), norms of vectors and matrices, matrix exponentials, and checks for properties like unitary or Hermitian matrices.

91.12 Applications of Linear Algebra

Sage can do many of the computations mentioned in the *Handbook of Linear Algebra.*

1. **Graphs** [Chapters 38-41]: Sage has a comprehensive graph theory and combinatorics library. See "Graph Theory" and "Combinatorics" in the Sage reference manual.
2. **Coding Theory** [Chapter 73]: Sage includes a number of codes and functionality related to coding theory. See the "Coding Theory" section of the reference manual.
3. **Linear Programming** [Chapters 68-69]: Sage comes with powerful linear programming, integer programming, and semidefinite programming tools, and also interfaces seamlessly with several industry solutions, such as CPLEX. See the "Numerical Tools" and "Numerical Optimization" sections of the reference manual.
4. **Minimum rank, zero forcing** [Chapter 46]: A Sage library that calculates minimum rank and zero forcing is at `https://github.com/jasongrout/minimum_rank`.

91.13 For More Information

1. **Web sites**: The main web site for Sage is `http://sagemath.org`. The main public Sage notebook server is `http://sagenb.org`.
2. **Sage help**: Access Sage documentation by clicking "Help" in the Sage Notebook or at `http://sagemath.org/doc`. Questions about how to use Sage should be addressed to either the sage-support mailing list, `http://groups.google.com/group/sage-support/`, or to the `http://ask.sagemath.org` web site. Discussion about Sage in education also happens on the sage-edu mailing list, `http://groups.google.com/group/sage-edu/`.
3. **Interacts**: Sage makes it very easy to create interactive demonstrations that utilize sliders, checkboxes, buttons, etc., allowing a user to easily adjust the inputs to a computation. See a number of examples at `http://wiki.sagemath.org/interact/` or the documentation for `interact()` (i.e., `interact?`) in the Sage notebook.
4. **Embedding Sage in a webpage**: Sage computations can easily be embedded in any webpage outside of the Sage notebook. A user can modify the Sage code, drag sliders, etc. See `https://sagecell.sagemath.org`.
5. **SageTeX**: Sage has a very easy way to embed Sage input and output directly into a LaTeX file. This allows an author to type Sage code directly into their LaTeX file, run the latex program (which generates a Sage code file), run Sage on the resulting Sage code file (which generates the outputs, graphics, etc.), and then run LaTeX again on their source file (which incorporates output and graphics back into the resulting pdf document). For example, to embed a Sage plot, merely type `\sageplot{plot(x^2, (x,0,4))}` in the LaTeX document, then run LaTeX, Sage, then LaTeX again to embed the plot in the pdf file. See the documentation for SageTeX in the Sage tutorial.
6. **Fortran support**: It is easy to compile and run FORTRAN code from within the Sage notebook. For examples, see *Numerical Sage* in the Sage documentation.

92.1 Introduction

A significant amount of execution time in complicated linear algebraic programs is known to be spent in a few low-level operations. Consequently, reducing the overall execution time of an application program leads to the problem of optimizing these low-level operations. Such low-level optimizations are highly machine-dependent and are a matter for specialists. A separation has, therefore, been made by the computational linear algebra community: On the one hand, highly efficient, machine-dependent building blocks of linear algebra, the BLAS (basic linear algebra subprograms), are provided on a given computational platform. On the other hand, linear algebra programs attempt to make the most use of those computational blocks in order to have as good performance as possible across a wide range of platforms.

The first major concerted effort to achieve agreement on the specification of a set of linear algebra kernels resulted in the Level-1 BLAS [LHK79]. The Level-1 BLAS specification and implementation are the result of a collaborative project in 1973 through 1977. The Level-1 BLAS were extensively and successfully exploited by LINPACK [DBM79], a software package for the solution of dense and banded linear equations and linear least squares problems.

With the advent of vector machines, hierarchical memory machines, and shared memory parallel machines, specifications for the Level-2 and -3 BLAS [DDD90a], [DDD90b], [DDH88a], [DDH88b], concerned with matrix–vector and matrix–matrix operations, respectively, were drawn up in 1984 through 1986 and 1987 to 1988. These specifications made it possible to construct new software to utilize the memory hierarchy of modern computers more effectively. In particular, the Level-3 BLAS allowed the construction of software based upon block-partitioned algorithms, typified by the linear algebra software package LAPACK (see Chapter 93).

In this chapter, we present information about the BLAS. We begin with a basic definition, then describe the calling sequences, report a number of facts, and finally conclude with a few examples.

Definitions:

Two-dimensional column-major format. A two-dimensional array is said to be in column-major format when its entries are stored by column. This is the way the Fortran language stores two-dimensional arrays. For example, the declaration `double precision A(2,2)` stores the entries of the 2-by-2 two-dimensional array in the one-dimensional order: `A(1,1)`, `A(2,1)`, `A(1,2)`, `A(2,2)`.

Row-major format. Storage of the entries by row. This is the way C stores two-dimensional arrays.

Packed format. The packed format is relevant for symmetric, Hermitian, or triangular matrices. Half of the matrix (either the upper part or the lower part depending on a `UPLO` parameter) is stored in a one-dimensional array. For example, if `UPLO='L'`, the 3-by-3 symmetric matrix `A` is stored as `A(1,1)`, `A(2,1)`, `A(3,1)`, `A(2,2)`, `A(3,2)`, `A(3,3))`.

Leading dimension. In column-major format, the leading dimension is the first dimension of a two-dimensional array (as opposed to the dimension of the matrix stored in that array). The leading dimension of an array is necessary to access its elements. For example, if `LDA` is the leading dimension of `A`, and `A` is stored in the two-dimensional column-major format, $A_{i,j}$ is stored in position $i + (j - 1) * LDA$. The leading dimension of an m-by-n matrix is often m. It enables convenient abstraction to access submatrices (see examples). An m-by-n matrix should have `LDA` $\geq m$.

Increment. The increment of a vector is the number of storage elements from one element to the next. If the increment of a vector is 1, this means that the vector is stored contiguously in memory; an increment of 2 corresponds to using every other array element. The increment is useful to manipulate rows of a matrix stored in column-major format (see Example 3).

BLAS vector description. A vector description in BLAS is defined by three quantities — a vector length, an array or a starting element within an array, and the increment. This gives `(n,X,1)` for a vector of size `n` starting at index `X` with increment of `1`.

BLAS description of a general matrix. A general matrix is described in BLAS by four quantities: a `TRANS` label (`'N'` , `'T'`, or `'H'`), its dimensions `m` and `n`, an array or a starting element within an array, and a leading dimension. This gives `(TRANS,M,N,A,LDA)` if one wants to operate on the `TRANS` of an `M`-by-`N` matrix starting in `A(1,1)` and stored in an array of leading dimension `LDA`.

Prefixes The first letter of the name of a BLAS routine indicates the Fortran type on which it operates.

S - REAL	C - COMPLEX
D - DOUBLE PRECISION	Z - COMPLEX*16

Prefixes for Level-2 and Level-3 BLAS
Matrix types:

GE - GEneral	GB - General Band	
SY - SYmmetric	SB - Sym. Band	SP - Sym. Packed
HE - HErmitian	HB - Herm. Band	HP - Herm. Packed
TR - TRiangular	TB - Triang. Band	TP - Triang. Packed

Level-2 and Level-3 BLAS Options

TRANS = '**N**o transpose', '**T**ranspose', '**C**onjugate transpose'

UPLO = '**U**pper triangular', '**L**ower triangular'

DIAG = '**N**on-unit triangular', '**U**nit triangular'

SIDE = '**L**eft', '**R**ight' on the right)

Calls:

1. Below is the calling sequence for the `GEMV` matrix-vector multiply subroutine. The `GEMV` routine performs the mathematical operation

$$y \longleftarrow \alpha Ax + \beta y, \quad \text{or} \quad y \longleftarrow \alpha A^T x + \beta y.$$

For double precision, the calling sequence looks like

```
      SUBROUTINE DGEMV ( TRANS, M, N, ALPHA, A, LDA, X, INCX,
     $                   BETA, Y, INCY )
```

The types of the variables are as follows:

```
      DOUBLE PRECISION   ALPHA, BETA
      INTEGER            INCX, INCY, LDA, M, N
      CHARACTER*1        TRANS
      DOUBLE PRECISION   A( LDA, * ), X( * ), Y( * )
```

The meaning of the variables is as follows:

`TRANS` : Specifies the operation to be performed as
`TRANS='N'` $y \leftarrow \alpha Ax + \beta y$,
`TRANS='T'` $y \leftarrow \alpha A^T x + \beta y$.

`M` : Specifies the number of rows of the matrix A.

`N` : Specifies the number of columns of the matrix A.

`ALPHA`: Specifies the scalar α.

`A` : Points to the first entry of the two-dimensional array that stores the elements of A in column major format.

`LDA` : Specifies the leading dimension of A.

`X` : Points to the incremented array that contains the vector x.

`INCX` : Specifies the increment for the elements of `X`.

`BETA` : Specifies the scalar β.

`Y` : Points to the incremented array that contains the vector y.

`INCY` : Specifies the increment for the elements of `Y`.

All variables are left unchanged after completion of the routines, except `Y`.

2. The following table is the quick reference to the BLAS.

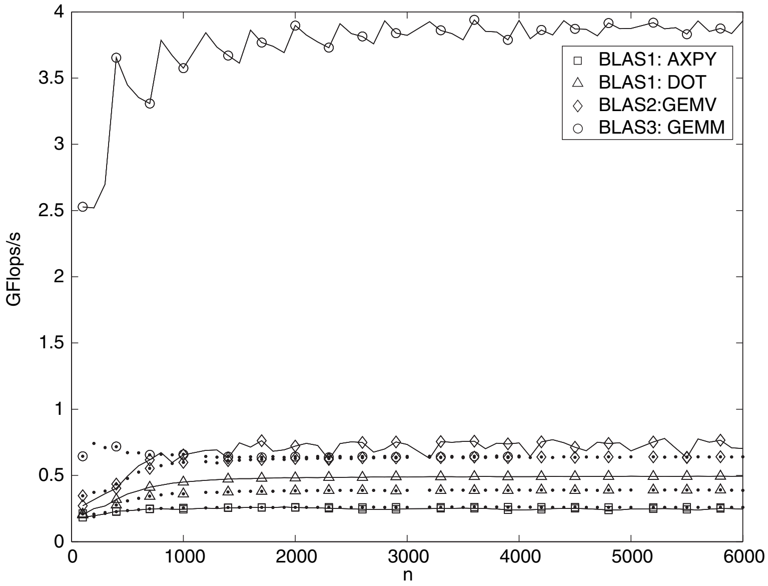

FIGURE 92.1 Performance in GFlops of four BLAS routines for two different BLAS libraries on an Intel Xeon CPU running at 3.20 GHz. The first BLAS library represents an optimized BLAS library (here, ATLAS v3.7.8), its four performance curves are given with a solid line on the graph. The second library represents straightforward implementation (here reference BLAS from netlib); its four performance curves are given with a dotted line on the graph. This graph illustrates two facts: An optimized Level-3 BLAS is roughly five times faster than Level-1 or Level-2 BLAS and it is also roughly five times faster than a reference Level-3 BLAS implementation. To give an idea of the actual time, multiplying two 6000-by-6000 matrices on this machine will take about 2 minutes using the ATLAS BLAS while it will take about 10 minutes using the reference BLAS implementation.

Facts:

1. The BLAS represent fairly simple linear algebra kernels that are easily coded in a few lines. One could also download reference source codes and compile them (`http://www.netlib.org/blas`). However, this strategy is unlikely to give good performance, no matter the level of sophistication of the compiler. The recommended way to obtain an efficient BLAS is to use vendor BLAS libraries, or to install the ATLAS [WPD01] package. Figure 92.1 illustrates the fact that ATLAS BLAS clearly outperform the reference implementation for the matrix–matrix multiply by a factor of five on a modern architecture.
2. To a great extent, the user community has embraced the BLAS, not only for performance reasons, but also because developing software around a core of common routines like the BLAS is good software engineering practice. Highly efficient, machine-specific implementations of the BLAS are available for most modern high-performance computers. To obtain an up-to-date list of available optimized BLAS, see the BLAS FAQ at `http://www.netlib.org/blas`.
3. Level-1 BLAS operates on $\mathcal{O}(n)$ data and performs $\mathcal{O}(n)$ operations. Level-2 BLAS operates on $\mathcal{O}(n^2)$ data and performs $\mathcal{O}(n^2)$ operations. Level-3 BLAS operates on $\mathcal{O}(n^2)$ data and performs $\mathcal{O}(n^3)$ operations. Therefore, the ratio operation/data is $\mathcal{O}(1)$ for Level-1 BLAS and Level-2 BLAS, but $\mathcal{O}(n)$ for Level-3 BLAS. On modern architecture, where memory access is particularly slow compared to computation time, Level-3 BLAS exploit this $\mathcal{O}(n)$ ratio to mask the memory access bottleneck (latency and bandwidth). Figure 92.1 illustrates the fact that Level-3 BLAS on a

modern architecture performs five times more floating-point operations per second than a Level-2 or Level-1 BLAS routine. Most of the linear algebra libraries try to make as much as possible use of Level-3 BLAS.

4. Most of shared memory computers have a multithreaded BLAS library. By programming a sequential code and linking with the multithreaded BLAS library, the application will use all the computing units of the shared memory system without any explicit parallelism in the user application code.
5. Although here we present only calling sequences from Fortran, it is possible to call the BLAS from C. The major problem for C users is the Fortran interface used by the BLAS. The data layout (the BLAS interface assumes column-major format) and the passage of parameters by reference (as opposed to values) has to be done carefully. See Example 2 for an illustration. Nowadays most BLAS distributions provide a C-interface to the BLAS. This solves these two issues and, thus, we highly recommend its use.
6. The Level-1, Level-2, and Level-3 BLAS are now extended by a new standard with more functionality and better software standard; see [BDD02], [Don02]. For example, the C-interface to the BLAS (see Fact 5) is included in this new BLAS.

Examples:

In all of these examples, A is an m-by-n matrix and it is stored in an `M`-by-`N` array starting at position `A`, B is an n-by-n matrix and it is stored in an `N`-by-`N` array starting at position `B`, C is an m-by-m matrix and it is stored in an `M`-by-`M` array starting at position `C`, X is a vector of size n and it is stored in an `N` array starting at position `X`, and Y is a vector of size m and it is stored in an `M` array starting at position `Y`. All the two-dimensional arrays are in column-major format, all the one-dimensional arrays have increment one. We assume that m and n are both greater than 11 in Example 3.

1. To perform the operation $y \longleftarrow Ax$ the BLAS calling sequence is

   ```
   CALL DGEMV ( ’N’, M, N, 1.0D0, A, M, X, 1, 0.0D0, Y, 1 )
   ```

2. To perform the operation $x \longleftarrow \alpha A^T y + \beta x$ the BLAS calling sequence is

   ```
   CALL DGEMV ( ’T’, M, N, ALPHA, A, M, Y, 1, BETA, X, 1 )
   ```

   From C, this would give

   ```
   IONE = 1;
   dgemv ( "T", &M, &N, &ALPHA, A, &M, Y, &IONE, &BETA, X, &IONE );
   ```

3. To perform the operation
   $y(2:10) \longleftarrow 2A(3:11, 4:11) * B(4, 3:10)^T - 3y(2:10)$;
   the BLAS calling sequence is

   ```
   CALL DGEMV ( ’N’, 9, 8, 2.0D0, A(3,4), M, B(4,3), N, -3.0D0,

   Y(2), 1 )
   ```

   (Note the use of `LDA` to operate on the submatrix of A and the use of `INCX` to operate on a row of B.)
4. LAPACK (see Chapter 93) is a library based on the BLAS. Opening its Fortran files enables one to gain a good understanding of how to use BLAS routines. For example, a good way to start is to have a look at `dgetrf.f`, which performs a right-looking LU factorization by making calls to `DTRSM` and `DGEMM`.

93.1 Introduction

LAPACK (linear algebra package) is an open source library of programs for solving the most commonly occurring numerical linear algebra problems [ABB99]. Complete documentation as well as source codes are available online at the Netlib repository [LAP]. LAPACK provides driver routines for solving complete problems such as linear equations, linear least squares problems, eigenvalue problems, and singular value problems. Each driver routine calls a sequence of computational routines, each of which performs a distinct computational task. In addition, LAPACK provides comprehensive error bounds for most computed quantities. LAPACK is designed to be portable for sequential and shared memory machines with deep memory hierarchies, in which most performance issues could be reduced to providing optimized versions of the Basic Linear Algebra Subroutines (BLAS) (See Chapter 92).

LAPACK is written in Fortran 90. There have been a number of extensions of LAPACK. CLAPACK is built using the Fortran to C (f2c) conversion utilities, respectively [CLA]. ScaLAPACK is a portable implementation of some of the core routines in LAPACK for parallel distributed computing [SCA]. ScaLAPACK is designed for distributed memory machines with very powerful homogeneous sequential processors and with homogeneous network interconnections. PLASMA (Parallel Linear Algebra for Scalable Multi-core Architectures) [PLA] and MAGMA (Matrix Algebra on GPU and Multicore Architectures) projects [MAG] aim to develop dense linear algebra libraries similar to LAPACK but for heterogeneous/hybrid “Multicore+GPU” architectures.

The purpose of this chapter is to acquaint the reader with 10 essential numerical linear algebra problems and LAPACK’s way of solving those problems. The reader may find it helpful to consult Chapter 92, where some of the terms used here are defined. The following table summarizes these problems and sections that are treated in LAPACK.

Type of Problem	Acronyms	Section
Linear system of equations	SV	93.2
Linear least squares problems	LLS	93.3
Linear equality-constrained least squares problem	LSE	93.4
General linear model problem	GLM	93.5
Symmetric eigenproblems	SEP	93.6
Nonsymmetric eigenproblems	NEP	93.7
Singular value decomposition	SVD	93.8
Generalized symmetric definite eigenproblems	GSEP	93.9
Generalized nonsymmetric eigenproblems	GNEP	93.10
Generalized (or quotient) singular value decomposition	GSVD (QSVD)	93.11

Sections have been subdivided into the following headings: (1) Definition: defines the problem, (2) Background: discusses the background of the problem and references to the related sections in this handbook, (3) Driver Routines: describes different types of driver routines available that solve the same problem, (4) Examples: specifies the calling sequence for a driver routine that solves the problem followed by numerical examples.

All LAPACK routines are available in four data types, as indicated by the initial letter "x" of each subroutine name: x = "S" means real single precision, x = "D", real double precision, x = "C", complex single precision, and x = "Z", complex*16 or double complex precision. In single precision (and complex single precision), the computations are performed with a unit roundoff of 5.96×10^{-8}. In double precision (and complex double precision), the computations are performed with a unit roundoff of 1.11×10^{-16}.

All matrices are assumed to be stored in column-major format. The software can also handle submatrices of matrices, even though these submatrices may not be stored in consecutive memory locations. For example, to specify the 10-by-10 submatrix lying in rows and columns 11 through 20 of a 30-by-30 matrix A, one must specify

- `A(11, 11)`, the upper left corner of the submatrix
- `30` = Leading dimension of `A` in its declaration (often denoted `LDA` in calling sequences)
- `10` = Number of rows of the submatrix (often denoted `M`, can be at most `LDA`)
- `10` = Number of columns of submatrix (often denoted `N`)

All matrix arguments require these four parameters (some subroutines may have fewer inputs if, for example, the submatrix is assumed square so that $\mathrm{M} = \mathrm{N}$). (See Chapter 92, for more details.)

Most of the LAPACK routines require the users to provide them a workspace (`WORK`) and its dimension (`LWORK`). The *optimal* workspace dimension refers to the workspace dimension, which enables the code to have the best performance on the targeted machine. The computation of the optimal workspace dimension is often complex so that most of LAPACK routines have the ability to compute it. If a LAPACK routine is called with `LWORK=-1`, then a workspace query is assumed. The routine only calculates the optimal size of the `WORK` array and returns this value as the first entry of the `WORK` array. If a larger workspace is provided, the extra part is not used, so that the code runs at the optimal performance. A *minimal* workspace dimension is provided in the document of routines. If a routine is called with a workspace dimension smaller than the minimal workspace dimension, the computation cannot be performed.

93.2 Linear System of Equations

Definitions:

The **problem of linear equations** is to compute a solution X of the system of linear equations

$$AX = B, \tag{93.1}$$

where A is an n-by-n matrix and X and B are n-by-m matrices.

Background:

The theoretical and algorithmic background of the solution of linear equations is discussed extensively in Chapter 50 through Chapter 54, especially Chapter 51.

Driver Routines:

There are two types of driver routines for solving the systems of linear equations — simple driver and expert driver. The expert driver solves the linear system and allows A to be replaced by A^T or A^*; and provides error bounds, condition number estimate, scaling, and can refine the solution. Each of these types of drivers has different implementations that take advantage of the special properties or storage schemes of the matrix A, as listed in the following table.

	Routine Names	
Data Structure (Matrix Storage Scheme)	Simple Driver	Expert Driver
General dense	xGESV	xGESVX
General band	xGBSV	xGBSVX
General tridiagonal	xGTSV	xGTSVX
Symmetric/Hermitian positive definite	xPOSV	xPOSVX
Symmetric/Hermitian positive definite (packed storage)	xPPSV	xPPSVX
Banded symmetric positive definite	xPBSV	xPBSVX
Tridiagonal symmetric positive definite	xPTSV	xPTSVX
Symmetric/Hermitian indefinite	xSYSV/xHESV	xSYSVX/xHESVX
Symmetric/Hermitian indefinite (packed storage)	xSPSV/xHPSV	xSPSVX/xHPSVX
Complex symmetric	CSYSV/ZSYSV	CSYSVX/ZSYSVX

The prefixes GE (for general dense), GB (for general band), etc. have standard meanings for all the BLAS and LAPACK routines.

Examples:

1. Let us show how to use the simple driver routine SGESV to solve a general linear system of equations. SGESV computes the solution of a real linear equation (93.1) in single precision by first computing the LU decomposition with row partial pivoting of the coefficient matrix A, followed by the back and forward substitutions. SGESV has the following calling sequence:

```
CALL SGESV( N, NRHS, A, LDA, IPIV, B, LDB, INFO )
```

   Input to SGESV:

   `N`: The number of linear equations, i.e., the order of A. $\mathtt{N} \geq 0$.

   `NRHS`: The number of right-hand-sides, i.e., the number of columns of B. $\mathtt{NRHS} \geq 0$.

   `A, LDA`: The `N`-by-`N` coefficient matrix A and the leading dimension of the array `A`. $\mathtt{LDA} \geq \max(\mathtt{1}, \mathtt{N})$.

`B, LDB`: The `N`-by-`NRHS` matrix B and the leading dimension of the array `B`. `LDB` $\geq \max(1, \mathtt{N})$.

Output from `SGESV`:

`A`: The factors L and U from factorization $A = PLU$; the unit diagonal elements of L are not stored.

`IPIV`: The pivot indices that define the permutation matrix P; row i of the matrix was interchanged with row `IPIV`(i).

`B`: If `INFO` $= 0$, the `N`-by-`NRHS` solution X.

`INFO`: $= 0$, successful exit. If `INFO` $= -j$, the jth argument had an illegal value. If `INFO` $= j$, $U(j,j)$ is exactly zero. The factorization has been completed, but the factor U is singular, so the solution could not be computed.

Consider a 4-by-4 linear system of Eq. (93.1), where

$$A = \begin{bmatrix} 5 & 7 & 6 & 5 \\ 7 & 10 & 8 & 7 \\ 6 & 8 & 10 & 9 \\ 5 & 7 & 9 & 10 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 23 \\ 32 \\ 33 \\ 31 \end{bmatrix}.$$

The exact solution is $\mathbf{x} = \begin{bmatrix} 1 & 1 & 1 & 1 \end{bmatrix}^T$. Upon calling SGESV, the program successfully exits with `INFO` $= 0$ and the solution X of Eq. (93.1) resides in the array `B`

$$X = \begin{bmatrix} 0.9999998 \\ 1.0000004 \\ 0.9999998 \\ 1.0000001 \end{bmatrix}.$$

Since SGESV performs the computation in single precision arithmetic, it is normal to have an error of the order of 10^{-6} in the solution X. By reading the lower diagonal entries in the array `A` and filling the diagonal entries with ones, we recover the lower unit triangular matrix L of the LU factorization with row partial pivoting of A as follows:

$$L = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0.8571429 & 1 & 0 & 0 \\ 0.7142857 & 0.2500000 & 1 & 0 \\ 0.7142857 & 0.2500000 & -0.2000000 & 1 \end{bmatrix}.$$

The upper triangular matrix U is recovered by reading the diagonal and upper diagonal entries in `A`. That is:

$$U = \begin{bmatrix} 7.0000000 & 10.0000000 & 8.0000000 & 7.0000000 \\ 0 & -0.5714293 & 3.1428566 & 2.9999995 \\ 0 & 0 & 2.5000000 & 4.2500000 \\ 0 & 0 & 0 & 0.1000000 \end{bmatrix}.$$

Finally, the permutation matrix P is the identity matrix that exchanges its ith row with row `IPIV`(i), for $i = n, \ldots, 1$. Since

$$\mathtt{IPIV} = \begin{bmatrix} 2 & 3 & 4 & 4 \end{bmatrix},$$

we have

$$P = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}.$$

93.3 Linear Least Squares Problems

Definitions:

The **linear least squares (LLS) problem** is to find

$$\min_{\mathbf{x}} \|\mathbf{b} - A\mathbf{x}\|_2, \tag{93.2}$$

where A is an m-by-n matrix and $\mathbf{b}$ is an m element vector.

Background:

The most usual case is $m \geq n$ and $\text{rank}(A) = n$. In this case, the solution to the LLS problem (93.2) is unique, and the problem is also referred to as finding a least squares solution to an overdetermined system of linear equations. When $m < n$ and $\text{rank}(A) = m$, there are an infinite number of solutions $\mathbf{x}$ that exactly satisfy $\mathbf{b} - A\mathbf{x} = 0$. In this case, it is often useful to find the unique solution $\mathbf{x}$ that minimizes $\|\mathbf{x}\|_2$, and the problem is referred to as finding a minimum norm solution to an underdetermined system of linear equations. (See Chapter 5 and Chapter 52 for more information on linear least squares problems.)

Driver Routines:

There are four types of driver routines that solve the LLS problem (93.2) and also allow A to be replaced by A^*. In the general case when $\text{rank}(A) < \min(m, n)$, we seek the minimum norm least squares solution $\mathbf{x}$ that minimizes both $\|\mathbf{x}\|_2$ and $\|\mathbf{b} - A\mathbf{x}\|_2$. The types of driver routines are categorized by the methods used to solve the LLS problem, as shown in the following table.

Type of Matrix	Algorithm	Routine Names
General dense	QR or LQ factorization	xGELS
General dense	Complete orthogonal factorization	xGELSY
General dense	SVD	xGELSS
General dense	Divide-and-conquer SVD	xGELSD

xGELSD is significantly faster than xGELSS, but it demands somewhat more workspace depending on the matrix dimensions. Among these routines, only xGELS requires A to be full rank while xGELSY, xGELSS, and xGELSD allow less than full rank.

Note that all driver routines allow several right-hand-side vectors $\mathbf{b}$ and corresponding solutions $\mathbf{x}$ to be handled in a single call, storing these vectors as columns of matrices B and X, respectively. However, the LLS problem (93.2) is solved for each right-hand-side independently; that is not the same as finding a matrix X which minimizes $\|B - AX\|_2$.

Examples:

1. Let us show how to use the simple driver routine SGELS to solve the LLS problem (93.2). SGELS computes the QR decomposition of the matrix A, updates the vector $\mathbf{b}$, and then computes the solution $\mathbf{x}$ by back substitution. SGELS has the following calling sequence:

   ```
   CALL SGELS( TRANS, M, N, NRHS, A, LDA, B, LDB, WORK, LWORK, INFO )
   ```

   Input to `SGELS`:

   `TRANS: = 'N'` or `'T'`: solves the LLS with A or A^T.

   `M, N`: The numbers of rows and columns of the matrix A. `M` $\geq$ `0` and `N` $\geq$ `0`.

   `M, NRHS`: The number of rows and columns of the matrices B and X. `NRHS` $\geq$ `0`.

`A, LDA`: The `M`-by-`N` matrix A and the leading dimension of the array `A`. $\texttt{LDA} \geq \max(\texttt{1}, \texttt{M})$.

`B, LDB`: The matrix B and the leading dimension of the array `B`. $\texttt{LDB} \geq \max(\texttt{1}, \texttt{M}, \texttt{N})$.
If `TRANS = 'N'`, then B is `M`-by-`NRHS`. If `TRANS = 'T'`, then B is `N`-by-`NRHS`.

`WORK, LWORK`: The workspace array and its dimension.
$\texttt{LWORK} \geq \min(\texttt{M}, \texttt{N}) + \max(\texttt{1}, \texttt{M}, \texttt{N}, \texttt{NRHS})$.
If $\texttt{LWORK} = -1$, then a workspace query is assumed; the routine only calculates the optimal size of the `WORK` array, and returns this value as the first entry of the `WORK` array.

Output from `SGELS`:

`B`: It is overwritten by the solution vectors, stored columnwise.

- If $\texttt{TRANS} = \texttt{'N'}$ and $\texttt{M} \geq \texttt{N}$, rows 1 to `N` of `B` contain the solution vectors of the LLS problem $\min_{\mathbf{x}} \|\mathbf{b} - A\mathbf{x}\|_2$; the residual sum of squares in each column is given by the sum of squares of elements $\texttt{N} + \texttt{1}$ to `M` in that column;
- If $\texttt{TRANS} = \texttt{'N'}$ and $\texttt{M} < \texttt{N}$, rows 1 to `N` of `B` contain the minimum norm solution vectors of the underdetermined system $AX = B$;
- If $\texttt{TRANS} = \texttt{'T'}$ and $\texttt{M} \geq \texttt{N}$, rows 1 to `M` of `B` contain the minimum norm solution vectors of the underdetermined system $A^T X = B$;
- If $\texttt{TRANS} = \texttt{'T'}$ and $\texttt{M} < \texttt{N}$, rows 1 to `M` of `B` contain the solution vectors of the LLS problem $\min_{\mathbf{x}} \|\mathbf{b} - A^T\mathbf{x}\|_2$; the residual sum of squares for the solution in each column is given by the sum of the squares of elements `M+1` to `N` in that column.

`WORK`: If $\texttt{INFO} = 0$, `WORK(1)` returns the optimal `LWORK`.

`INFO`: $\texttt{INFO} = 0$ if successful exit. If $\texttt{INFO} = -j$, the jth input argument had an illegal value.

Consider an LLS problem (93.2) with a 6-by-5 matrix A and a 6-by-1 matrix $\mathbf{b}$:

$$A = \begin{bmatrix} -74 & 80 & 18 & -11 & -4 \\ 14 & -69 & 21 & 28 & 0 \\ 66 & -72 & -5 & 7 & 1 \\ -12 & 66 & -30 & -23 & 3 \\ 3 & 8 & -7 & -4 & 1 \\ 4 & -12 & 4 & 4 & 0 \end{bmatrix} \quad \text{and} \quad \mathbf{b} = \begin{bmatrix} 51 \\ -61 \\ -56 \\ 69 \\ 10 \\ -12 \end{bmatrix}.$$

The exact solution of the LLS problem is $\mathbf{x} = \begin{bmatrix} 1 & 2 & -1 & 3 & -4 \end{bmatrix}^T$ with residual $\|\mathbf{b} - A\mathbf{x}\|_2 = 0$. Upon calling SGELS, the first five elements of `B` are overwritten by the solution vector $\mathbf{x}$:

$$\mathbf{x} = \begin{bmatrix} 1.0000176 \\ 2.0000196 \\ -0.9999972 \\ 3.0000386 \\ -4.0000405 \end{bmatrix},$$

while the sixth element of `B` contains the residual sum of squares 0.0000021. With $\texttt{M} = \texttt{6}, \texttt{N} = \texttt{5}$, $\texttt{NRHS} = \texttt{1}$, `LWORK` has been set to 11. For such a small matrix, the minimal workspace is also the optimal workspace.

93.4 The Linear Equality-Constrained Least Squares Problem

Definitions:

The **linear equality-constrained least squares (LSE) problem** is

$$\min_{\mathbf{x}} \|\mathbf{c} - A\mathbf{x}\|_2 \quad \text{subject to} \quad B\mathbf{x} = \mathbf{d}, \tag{93.3}$$

where A is an m-by-n matrix and B is a p-by-n matrix, $\mathbf{c}$ is an m-vector, and $\mathbf{d}$ is a p-vector, with $p \le n \le m + p$.

Background:

Under the assumptions that B has full row rank p and the matrix $\begin{bmatrix} A \\ B \end{bmatrix}$ has full column rank n, the LSE problem (93.3) has a unique solution $\mathbf{x}$.

Driver Routines:

The driver routine for solving the LSE is xGGLSE, which uses a generalized QR factorization of the matrices A and B.

Examples:

1. Let us show how to use the driver routine SGGLSE to solve the LSE problem (93.3). SGGLSE first computes a generalized QR decomposition of A and B, and then computes the solution by back substitution. SGGLSE has the following calling sequence:

   ```
   CALL SGGLSE( M, N, P, A, LDA, B, LDB, C, D, X, WORK, LWORK, INFO )
   ```

   Input to `SGGLSE`:

   `M, P`: The numbers of rows of the matrices A and B, respectively. `M` $\geq$ `0` and `P` $\geq$ `0`.

   `N`: The number of columns of the matrices A and B. `N` $\geq$ `0`. Note that `0` $\leq$ `P` $\leq$ `N` $\leq$ `M+P`.

   `A, LDA`: The `M`-by-`N` matrix A and the leading dimension of the array `A`. `LDA` $\geq$ max(`1`,`M`).

   `B, LDB`: The `P`-by-`N` matrix B and the leading dimension of the array `B`. `LDB` $\geq$ max(`1`,`P`).

   `C, D`: The right-hand-side vectors for the least squares part, and the constrained equation part of the LSE, respectively.

   `WORK, LWORK`: The workspace array and its dimension. `LWORK` $\geq$ max(`1`, `M` + `N` + `P`). If `LWORK` $= -1$, then a workspace query is assumed; the routine only calculates the optimal size of the `WORK` array, and returns this value as the first entry of the `WORK` array.

   Output from `SGGLSE`:

   `C`: The residual sum of squares for the solution is given by the sum of squares of elements `N-P+1` to `M` of vector `C`.

   `X`: The solution of the LSE problem.

   `WORK`: If `INFO = 0`, `WORK(1)` returns the optimal `LWORK`.

   `INFO`: $= 0$ if successful exit. If `INFO` $= -j$, the jth argument had an illegal value.

Let us demonstrate the use of SGGLSE to solve the LSE problem (93.3), where

$$A = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 3 & 1 \\ 1 & -1 & 1 \\ 1 & 1 & 1 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & -1 \end{bmatrix}, \quad \mathbf{c} = \begin{bmatrix} 1 \\ 2 \\ 3 \\ 4 \end{bmatrix}, \quad \mathbf{d} = \begin{bmatrix} 7 \\ 4 \end{bmatrix}.$$

The unique exact solution is $\mathbf{x} = \frac{1}{8}[46 \quad -2 \quad 12]^T$. Upon calling SGGLSE with this input data and $\texttt{M} = 4, \texttt{N} = 3, \texttt{P} = 2, \texttt{LWORK} = 9$, an approximate solution of the LSE problem is returned in `X`:

$$X = [5.7500000 \quad -0.2500001 \quad 1.4999994]^T.$$

The array `C` is overwritten by the residual sum of squares for the solution:

$$\texttt{C} = [4.2426405 \quad 8.9999981 \quad 2.1064947 \quad 0.2503501]^T.$$

93.5 A General Linear Model Problem

Definitions:

The **general linear model (GLM) problem** is

$$\min_{\mathbf{x},\mathbf{y}} \|\mathbf{y}\|_2 \quad \text{subject to} \quad \mathbf{d} = A\mathbf{x} + B\mathbf{y}, \tag{93.4}$$

where A is an n-by-m matrix, B is an n-by-p matrix, and $\mathbf{d}$ is a n-vector, with $m \leq n \leq m + p$.

Background:

When $B = I$, the problem reduces to an ordinary linear least squares problem (93.2). When B is square and nonsingular, the GLM problem is equivalent to the weighted linear least squares problem:

$$\min_{\mathbf{x}} \|B^{-1}(\mathbf{d} - A\mathbf{x})\|_2.$$

Since the GLM is equivalent to the LSE problem

$$\min_{\mathbf{x},\mathbf{y}} \left\| 0 - \begin{bmatrix} 0 & I \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} \right\|_2 \quad \text{subject to} \quad \begin{bmatrix} A & B \end{bmatrix} \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix} = \mathbf{d},$$

the GLM problem has a unique solution if the matrix $\begin{bmatrix} 0 & I \\ A & B \end{bmatrix}$ has full column rank $m + p$.

Driver Routines:

The driver routine for solving the GLM problem (93.4) is xGGGLM, which uses a generalized QR factorization of the matrices A and B.

Examples:

1. Let us show how to use the driver routine SGGGLM to solve the GLM problem (93.4). SGGGLM computes a generalized QR decomposition of the matrices A and B, and then computes the solution by back substitution. SGGGLM has the following calling sequence:

   ```
   CALL SGGGLM( N, M, P, A, LDA, B, LDB, D, X, Y, WORK, LWORK, INFO )
   ```

   Input to `SGGGLM`:

`N`: The number of rows of the matrices A and B. `N` $\geq$ `0`.

`M, P`: The number of columns of the matrices A and B, respectively. `0` $\leq$ `M` $\leq$ `N` and `P` $\geq$ `N-M`.

`A, LDA`: The `N`-by-`M` matrix A and the leading dimension of the array `A`. `LDA` $\geq$ max(`1`,`N`).

`B, LDB`: The `N`-by-`P` matrix B and the leading dimension of the array `B`. `LDB` $\geq$ max(`1`,`N`).

`D`: The left-hand-side of the GLM equation.

`WORK, LWORK`: The workspace array and its dimension. `LWORK` $\geq$ max(`1`,`N+M+P`). If `LWORK = -1`, then a workspace query is assumed; the routine only calculates the optimal size of the `WORK` array, and returns this value as the first entry of the `WORK` array.

Output from `SGGGLM`:

`X, Y`: Solution vectors.

`WORK`: If `INFO = 0`, `WORK(1)` returns the optimal `LWORK`.

`INFO`: `INFO = 0` if successful exit. If `INFO` $= -j$, the jth argument had an illegal value.

Let us demonstrate the use of SGGGLM for solving the GLM problem (93.4), where

$$A = \begin{bmatrix} 1 & 2 & 1 & 4 \\ -1 & 1 & 1 & 1 \\ -1 & -2 & -1 & 1 \\ -1 & 2 & -1 & -1 \\ 1 & 1 & 1 & 2 \end{bmatrix}, \quad B = \begin{bmatrix} 1 & 2 & 2 \\ -1 & 1 & -2 \\ 3 & 1 & 6 \\ 2 & -2 & 4 \\ 1 & -1 & 2 \end{bmatrix}, \quad \mathbf{d} = \begin{bmatrix} 7.99 \\ 0.98 \\ -2.98 \\ 3.04 \\ 4.02 \end{bmatrix}.$$

Upon calling SGGGLM with this input data, $\texttt{N} = \texttt{5}, \texttt{M} = \texttt{4}, \texttt{P} = \texttt{3}, \texttt{LWORK} = \texttt{12}$, the program successfully exits and returns the following solution vectors:

$$X = [1.002950 \quad 2.001435 \quad -0.987797 \quad 0.009080]^T$$

and

$$Y = [0.003435 \quad -0.004417 \quad 0.006871]^T.$$

93.6 Symmetric Eigenproblems

Definitions:

The **symmetric eigenvalue problem (SEP)** is to find the eigenvalues, λ, and corresponding eigenvectors, $\mathbf{x} \neq 0$, such that

$$A\mathbf{x} = \lambda\mathbf{x}, \tag{93.5}$$

where A is real and symmetric.

If A is complex and Hermitian, i.e., $A^* = A$, then it is referred to as the **Hermitian eigenvalue problem**.

Background:

When all eigenvalues and eigenvectors have been computed, we write

$$A = X\Lambda X^*, \tag{93.6}$$

where Λ is a diagonal matrix whose diagonal elements are real and are the eigenvalues, and X is an orthogonal (or unitary) matrix whose columns are the eigenvectors. This is the classical spectral decomposition of A. The theoretical and algorithmic backgrounds of the solution of the symmetric eigenvalue problem are discussed in Chapter 55.

Driver Routines:

There are four types of driver routines for solving the SEP (93.5) and each has its own variations that take advantage of the special structure or storage of the matrix A, as summarized in the following table.

Types of Matrix (Storage Scheme)	Routine Names			
	Simple Driver	Divide-and-Conquer	Expert Driver	RRR Driver
General symmetric	xSYEV	xSYEVD	xSYEVX	xSYEVR
General symmetric (packed storage)	xSPEV	xSPEVD	xSPEVX	–
Band matrix	xSBEV	xSBEVD	xSBEVX	–
Tridiagonal matrix	xSTEV	xSTEVD	xSTEVX	xSTEVR

The simple driver computes all eigenvalues and (optionally) eigenvectors. The expert driver computes all or a selected subset of the eigenvalues and (optionally) eigenvectors. The divide-and-conquer driver has the same functionality as, yet outperforms, the simple driver, but it requires more workspace. The relative robust representation (RRR) driver computes all or a subset of the eigenvalues and (optionally) the eigenvectors. The last one is generally faster than any other type of driver routine and uses the least amount of workspace.

Examples:

1. Let us show how to use the simple driver SSYEV to solve the SEP (93.5) by computing the spectral decomposition (93.6). SSYEV first reduces A to a tridiagonal form, and then uses the implicit QL or QR algorithm to compute eigenvalues and optionally eigenvectors. SSYEV has the following calling sequence:

   ```
   CALL SSYEV( JOBZ, UPLO, N, A, LDA, W, WORK, LWORK, INFO )
   ```

   Input to `SSYEV`:

   `JOBZ`: = `'N'`, compute eigenvalues only;
   = `'V'`, compute eigenvalues and eigenvectors.

   `UPLO`: = `'U'`, the upper triangle of A is stored in the array `A`; if `UPLO = 'L'`, the lower triangle of A is stored.

   `N`: The order of the matrix A. `N` $\geq$ `0`.

   `A, LDA`: The symmetric matrix A and the leading dimension of the array `A`. `LDA` $\geq$ max(`1`,`N`).

   `WORK, LWORK`: The workspace array and its dimension. `LWORK` $\geq \max(1, 3 * N - 1)$. If `LWORK` $= -1$, then a workspace query is assumed; the routine only calculates the optimal size of the `WORK` array, and returns this value as the first entry of the `WORK` array.

   Output from `SSYEV`:

   `A`: The orthonormal eigenvectors X, if `JOBZ = 'V'`.

`W`: The eigenvalues λ in ascending order.

`WORK`: If `INFO = 0`, `WORK(1)` returns the optimal `LWORK`.

`INFO`: $=$ `0` if successful exit. If `INFO` $= -j$, the jth input argument had an illegal value. If `INFO` $= j$, the j off-diagonal elements of an intermediate tridiagonal form did not converge to zero.

Let us demonstrate the use of SSYEV to solve the SEP (93.5), where

$$A = \begin{bmatrix} 5 & 4 & 1 & 1 \\ 4 & 5 & 1 & 1 \\ 1 & 1 & 4 & 2 \\ 1 & 1 & 2 & 4 \end{bmatrix}.$$

The exact eigenvalues are 1, 2, 5, and 10. Upon calling SSYEV with the matrix A and `N` $= 4$, `LWORK` $=$ `3` $*$ `N`$-$ `1` $=$ `11`, `A` is overwritten by its orthonormal eigenvectors X.

$$X = \begin{bmatrix} 0.7071068 & -0.0000003 & 0.3162279 & 0.6324555 \\ -0.7071068 & 0.0000001 & 0.3162278 & 0.6324555 \\ 0.0000002 & 0.7071069 & -0.6324553 & 0.3162278 \\ -0.0000001 & -0.7071066 & -0.6324556 & 0.3162278 \end{bmatrix}.$$

The eigenvalues that correspond to the eigenvectors in each column of `X` are returned in `W`:

$$\texttt{W} = [0.9999996 \quad 1.9999999 \quad 4.9999995 \quad 10.0000000].$$

93.7 Nonsymmetric Eigenproblems

As is customary in numerical linear algebra, in this section the term **left eigenvector** of A means a (column) vector $\mathbf{y}$ such that $\mathbf{y}^*A = \lambda\mathbf{y}^*$. This is contrary to the definition in Section 4.4, under which $\mathbf{y}^*$ would be called a left eigenvector.

Definitions:

The nonsymmetric eigenvalue problem (NEP) is to find the eigenvalues, λ, and corresponding (right) eigenvectors, $\mathbf{x} \neq 0$, such that

$$A\mathbf{x} = \lambda\mathbf{x} \tag{93.7}$$

and, perhaps, the left eigenvectors, $\mathbf{y} \neq 0$, satisfying

$$\mathbf{y}^*A = \lambda\mathbf{y}^*. \tag{93.8}$$

Background:

The problem is solved by computing the Schur decomposition of A, defined in the real case as

$$A = ZTZ^T,$$

where Z is an orthogonal matrix and T is an upper quasi-triangular matrix with 1-by-1 and 2-by-2 diagonal blocks, the 2-by-2 blocks corresponding to complex conjugate pairs of eigenvalues of A. In the complex case, the Schur decomposition is

$$A = ZTZ^*,$$

where Z is unitary and T is a complex upper triangular matrix.

The columns of Z are called the Schur vectors. For each k ($1 \leq k \leq n$), the first k columns of Z form an orthonormal basis for the invariant subspace corresponding to the first k eigenvalues on the diagonal of T. It is possible to order the Schur factorization so that any desired set of k eigenvalues occupies the k leading positions on the diagonal of T. The theoretical and algorithmic background of the solution of the nonsymmetric eigenvalue problem is discussed in Chapter 56.

Driver Routines:

Both the simple driver xGEEV and expert driver xGEEVX are provided. The simple driver computes all the eigenvalues of A and (optionally) the right or left eigenvectors (or both). The expert driver performs the same task as the simple driver plus the additional feature that it balances the matrix to try to improve the conditioning of the eigenvalues and eigenvectors, and it computes the condition numbers for the eigenvalues or eigenvectors (or both).

Examples:

1. Let us show how to use the simple driver SGEEV to solve the NEP (93.7). SGEEV first reduces A to an upper Hessenberg form (a Hessenberg matrix is a matrix where all entries below the first lower subdiagonal are zeros), and then uses the implicit QR algorithm to compute the Schur decomposition, and finally computes eigenvectors of the upper quasi-triangular matrix. SGEEV has the following calling sequence:

   ```
   CALL SGEEV( JOBVL, JOBVR, N, A, LDA, WR, WI, VL, LDVL, VR, LDVR, WORK, LWORK, INFO )
   ```

   Input to `SGEEV`:

   `JOBVL, JOBVR:` = `'V'`, the left and/or right eigenvectors are computed;
   = `'N'`, the left and/or right eigenvectors are not computed.

   `N:` The order of the matrix A. `N` $\geq$ `0`.

   `A, LDA:` The matrix A and the leading dimension of the array `A`. `LDA` $\geq \max(1, N)$.

   `LDVL, LDVR:` The leading dimensions of the arrays `VL` and `VR` if the left and right eigenvectors are computed. `LDVL, LDVR` $\geq$ `N`.

   `WORK, LWORK:` The workspace array and its dimension. `LWORK` $\geq \max(1, 3*N)$. If eigenvectors are computed, `LWORK` $\geq 4*N$. For good performance, `LWORK` must generally be larger.
   If `LWORK` $= -1$, then a workspace query is assumed; the routine only calculates the optimal size of the `WORK` array, and returns this value as the first entry of the `WORK` array.

   Output from `SGEEV`:

   `WR, WI:` The real and imaginary parts of the computed eigenvalues. Complex conjugate pairs of eigenvalues appear consecutively with the eigenvalue having the positive imaginary part first.

   `VL:` If the jth eigenvalue λ_j is real, then the jth left eigenvector $\mathbf{y}_j$ is stored in $\mathtt{VL}(:,j)$. If the jth and $(j+1)$-st eigenvalues λ_j and λ_{j+1} form a complex conjugate pair, then $\mathtt{VL}(:,j) + i \cdot \mathtt{VL}(:,j+1)$ and $\mathtt{VL}(:,j) - i \cdot \mathtt{VL}(:,j+1)$ are the corresponding left eigenvectors $\mathbf{y}_j$ and $\mathbf{y}_{j+1}$.

   `VR:` If the jth eigenvalue λ_j is real, then the jth right eigenvector $\mathbf{x}_j$ is stored in $\mathtt{VR}(:,j)$. If the jth and $(j+1)$-st eigenvalues λ_j and λ_{j+1} form a complex conjugate pair, then $\mathtt{VR}(:,j) + i \cdot \mathtt{VR}(:,j+1)$ and $\mathtt{VR}(:,j) - i \cdot \mathtt{VR}(:,j+1)$ are the corresponding right eigenvectors $\mathbf{x}_j$ and $\mathbf{x}_{j+1}$.

   `WORK:` If `INFO = 0`, `WORK(1)` returns the optimal `LWORK`.

   `INFO:` `= 0` if successful exit. If `INFO` $= -j$, the jth argument had an illegal value. If `INFO` $= j$, the QR algorithm failed to compute all the eigenvalues, and no eigenvectors have been computed; elements $\mathtt{j+1:N}$ of `WR` and `WI` contain eigenvalues, which have converged.

Let us demonstrate the use of SGEEV for solving the NEP (93.7), where

$$A = \begin{bmatrix} 4 & -5 & 0 & 3 \\ 0 & 4 & -3 & -5 \\ 5 & -3 & 4 & 0 \\ 3 & 0 & 5 & 4 \end{bmatrix}.$$

The exact eigenvalues are $12, 1 + i \cdot 5, 1 - i \cdot 5$, and 2. Upon calling SGEEV with this matrix and $\texttt{N} = \texttt{4}, \texttt{LWORK} = \texttt{4} * \texttt{N} = \texttt{16}$, each eigenvalue, λ_j, is retrieved by combining the jth entry in `WR` and `WI`. such that $\lambda_j = \texttt{WR}(j) + i \cdot \texttt{WI}(j)$. If $\texttt{WI}(j)$ is 0, then the jth eigenvalue is real. For this example, we have

$$\begin{aligned} \lambda_1 &= 12.0000000 \\ \lambda_2 &= 1.000000 + i \cdot 5.0000005 \\ \lambda_3 &= 1.000000 - i \cdot 5.0000005 \\ \lambda_4 &= 1.9999999. \end{aligned}$$

The left eigenvectors are stored in `VL`. Since the first and fourth eigenvalues are real, their eigenvectors are the corresponding columns in `VL`, that is, $\mathbf{y}_1 = \texttt{VL}(:, 1)$ and $\mathbf{y}_4 = \texttt{VL}(:, 4)$. Since the second and third eigenvalues form a complex conjugate pair, the second eigenvector, $\mathbf{y}_2 = \texttt{VL}(:, 2) + i \cdot \texttt{VL}(:, 3)$ and the third eigenvector, $\mathbf{y}_3 = \texttt{VL}(:, 2) - i \cdot \texttt{VL}(:, 3)$. If we place all the eigenvectors in a matrix Y where $Y = [\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3, \mathbf{y}_4]$, we have

$$Y = \begin{bmatrix} -0.5000001 & 0.0000003 - i \cdot 0.4999999 & 0.0000003 + i \cdot 0.4999999 & 0.5000000 \\ 0.4999999 & -0.5000002 & -0.5000002 & 0.5000001 \\ -0.5000000 & -0.5000000 - i \cdot 0.0000002 & -0.5000000 + i \cdot 0.0000002 & -0.4999999 \\ -0.5000001 & -0.0000003 + i \cdot 0.5000000 & -0.0000003 - i \cdot 0.5000000 & 0.5000001 \end{bmatrix}.$$

The right eigenvectors $\mathbf{x}_j$ can be recovered from `VR` in the way similar to the left eigenvectors. The right eigenvector matrix X is

$$X = \begin{bmatrix} -0.5000000 & 0.5000002 & 0.5000002 & 0.5000001 \\ 0.4999999 & -0.0000001 - i \cdot 0.5000000 & -0.0000001 + i \cdot 0.5000000 & 0.5000000 \\ -0.5000000 & -0.0000001 - i \cdot 0.4999999 & -0.0000001 + i \cdot 0.4999999 & -0.5000000 \\ -0.5000001 & -0.5000001 & -0.5000001 & 0.5000000 \end{bmatrix}.$$

93.8 Singular Value Decomposition

Definitions:

The **singular value decomposition (SVD)** of an m-by-n matrix A is

$$A = U \Sigma V^T \quad (A = U \Sigma V^* \quad \text{in the complex case}), \tag{93.9}$$

where U and V are orthogonal (unitary) and Σ is an m-by-n diagonal matrix with real diagonal elements, σ_j, such that

$$\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_{\min(m,n)} \geq 0.$$

The σ_j are the **singular values** of A and the first $\min(m, n)$ columns of U and V are the **left and right singular vectors** of A.

Background:

The singular values σ_j and the corresponding left singular vectors $\mathbf{u}_j$ and right singular vectors $\mathbf{v}_j$ satisfy

$$A\mathbf{v}_j = \sigma_j \mathbf{u}_j \quad \text{and} \quad A^T\mathbf{u}_j = \sigma_j \mathbf{v}_j \quad (\text{or} \quad A^*\mathbf{u_j} = \sigma_j \mathbf{v_j} \quad \text{in complex case}),$$

where $\mathbf{u_j}$ and $\mathbf{v_j}$ are the jth columns of U and V, respectively. (See Chapter 24 and Chapter 58 for more information on singular value decompositions.)

Driver Routines:

Two types of driver routines are provided in LAPACK. The simple driver xGESVD computes all the singular values and (optionally) left and/or right singular vectors. The divide and conquer driver xGESDD has the same functionality as the simple driver except that it is much faster for larger matrices, but uses more workspace.

Examples:

1. Let us show how to use the simple driver SGESVD to compute the SVD (93.9). SGESVD first reduces A to a bidiagonal form, and then uses an implicit QR-type algorithm to compute singular values and optionally singular vectors. SGESVD has the following calling sequence:

   ```
   CALL SGESVD( JOBU, JOBVT, M, N, A, LDA, S, U, LDU, VT, LDVT, WORK,
   LWORK, INFO )
   ```

   Input to `SGESVD`:

   `JOBU`: Specifies options for computing all or part of the left singular vectors U:
   = `'A'`, all `M` columns of U are returned in the array `U`:
   = `'S'`, the first min(`M`,`N`) columns of U are returned;
   = `'O'`, the first min(`M`,`N`) columns of U are overwritten on the array `A`;
   = `'N'`, no left singular vectors are computed. *Note that* `JOBVT` *and* `JOBU` *cannot both be* `'O'`.

   `JOBVT`: Specifies options for computing all or part of the right singular vectors $\mathtt{V}^\mathtt{T}$:
   = `'A'`, all `N` rows of V^T are returned in the array `VT`;
   = `'S'`, the first min(`M`,`N`) rows of V^T are returned;
   = `'O'`, the first min(`M`,`N`) rows of V^T are overwritten on the array `A`;
   = `'N'`, no right singular vectors are computed.

   `M, N`: The number of rows and columns of the matrix A. `M, N` $\geq$ `0`.

   `A, LDA`: The `M`-by-`N` matrix A and the leading dimension of the array `A`. `LDA` $\geq$ max(`1`,`M`).

   `LDU, LDVT`: The leading dimension of the arrays `U` and `VT`. `LDU`, `LDVT` $\geq$ `1`;
   If `JOBU = 'S' or 'A'`, `LDU` $\geq$ `M`.
   If `JOBVT = 'A'`, `LDVT` $\geq$ `N`; If `JOBVT = 'S'`, `LDVT` $\geq$ min(`M`, `N`).

   `WORK, LWORK`: The workspace array and its dimension. `LWORK` $\geq$ max(3 min(`M`, `N`)+ max(`M`, `N`), 5 min(`M`, `N`)).
   If `LWORK = -1`, then a workspace query is assumed; the routine only calculates the optimal size of the `WORK` array and returns this value as the first entry of the `WORK` array.

Output from `SGESVD`:

`A`: If `JOBU = 'O'`, `A` is overwritten with the first min(`M, N`) columns of U (the left singular vectors, stored columnwise);
If `JOBVT = 'O'`, `A` is overwritten with the first min(`M,N`) rows of V^T (the right singular vectors, stored rowwise);

`S`: Singular values of A, sorted so that $\mathtt{S}(i) \geq \mathtt{S}(i+1)$.

`U`: If `JOBU = 'A'`, `U` contains `M`-by-`M` orthogonal matrix U. If `JOBU = 'S'`, `U` contains the first min(`M,N`) columns of U. If `JOBU = 'N'` or `'O'`, `U` is not referenced.

`VT`: If `JOBVT = 'A'`, `VT` contains right `N`-by-`N` orthogonal matrix V^T. If `JOBVT = 'S'`, `VT` contains the first min(`M,N`) rows of $\mathtt{V}^{\mathrm{T}}$ (the right singular vectors stored row-wise). If `JOBVT = 'N'` or `'O'`, `VT` is not referenced.

`WORK`: If `INFO = 0`, `WORK(1)` returns the optimal `LWORK`.

`INFO`: $= 0$ if successful exit. If $\mathtt{INFO} = -j$, the jth argument had an illegal value. If $\mathtt{INFO} > 0$, the QR-type algorithm (subroutine SBDSQR) did not converge. `INFO` specifies how many superdiagonals of an intermediate bidiagonal form B did not converge to zero. `WORK`(2:min(`M,N`)) contains the unconverged superdiagonal elements of an upper bidiagonal matrix B whose diagonal is in `S` (not necessarily sorted). B satisfies $A = UBV^T$, so it has the same singular values as A, and singular vectors related by U and V^T.

Let us show the numerical results of SGESVD in computing the SVD by an 8-by-5 matrix A as follows:

$$A = \begin{bmatrix} 22 & 10 & 2 & 3 & 7 \\ 14 & 7 & 10 & 0 & 8 \\ -1 & 13 & -1 & -11 & 3 \\ -3 & -2 & 13 & -2 & 4 \\ 9 & 8 & 1 & -2 & 4 \\ 9 & 1 & -7 & 5 & -1 \\ 2 & -6 & 6 & 5 & 1 \\ 4 & 5 & 0 & -2 & 2 \end{bmatrix}.$$

The exact singular values are $\sqrt{1248}, 20, \sqrt{384}, 0, 0$. The rank of the matrix A is 3. Upon calling SGESVD with $\mathtt{M} = \mathtt{8}, \mathtt{N} = \mathtt{5}, \mathtt{LWORK} = \mathtt{25}$, the computed singular values of A are returned in `S`:

$$\mathtt{S} = [35.3270454 \quad 20.0000038 \quad 19.5959187 \quad 0.0000007 \quad 0.0000004].$$

The columns in `U` contain the left singular vectors U of A:

$$U = \begin{bmatrix} \text{-7.0711e-001} & \text{1.5812e-001} & \text{-1.7678e-001} & \text{2.4818e-001} & \text{-4.0289e-001} & \text{-3.2305e-001} & \text{-3.3272e-001} & \text{-6.9129e-002} \\ \text{-5.3033e-001} & \text{1.5811e-001} & \text{3.5355e-001} & \text{-6.2416e-001} & \text{2.5591e-001} & \text{-3.9178e-002} & \text{3.0548e-001} & \text{-1.3725e-001} \\ \text{-1.7678e-001} & \text{-7.9057e-001} & \text{1.7677e-001} & \text{3.0146e-001} & \text{1.9636e-001} & \text{-3.1852e-001} & \text{2.3590e-001} & \text{-1.6112e-001} \\ 0 & \text{1.5811e-001} & \text{7.0711e-001} & \text{2.9410e-001} & \text{3.1907e-001} & \text{4.7643e-002} & \text{-5.2856e-001} & \text{7.1055e-002} \\ \text{-3.5355e-001} & \text{-1.5811e-001} & \text{-1.0000e-006} & \text{2.3966e-001} & \text{-7.8607e-002} & \text{8.7800e-001} & \text{1.0987e-001} & \text{-5.8528e-002} \\ \text{-1.7678e-001} & \text{1.5812e-001} & \text{-5.3033e-001} & \text{1.7018e-001} & \text{7.9071e-001} & \text{-7.0484e-003} & \text{-9.0913e-002} & \text{-8.3220e-004} \\ 0 & \text{4.7434e-001} & \text{1.7678e-001} & \text{5.2915e-001} & \text{-1.5210e-002} & \text{-1.3789e-001} & \text{6.6193e-001} & \text{7.9763e-002} \\ \text{-1.7678e-001} & \text{-1.5811e-001} & \text{-1.0000e-006} & \text{-7.1202e-002} & \text{1.3965e-002} & \text{-2.0712e-002} & \text{4.9676e-002} & \text{9.6726e-001} \end{bmatrix}.$$

The rows in `VT` contain the right singular vectors V^T of A:

$$V^T = \begin{bmatrix} \text{-8.0064e-001} & \text{-4.8038e-001} & \text{-1.6013e-001} & 0 & \text{-3.2026e-001} \\ \text{3.1623e-001} & \text{-6.3246e-001} & \text{3.1622e-001} & \text{6.3246e-001} & \text{-1.8000e-006} \\ \text{-2.8867e-001} & \text{-3.9000e-006} & \text{8.6603e-001} & \text{-2.8867e-001} & \text{2.8868e-001} \\ \text{-4.0970e-001} & \text{3.4253e-001} & \text{-1.2426e-001} & \text{6.0951e-001} & \text{5.7260e-001} \\ \text{8.8224e-002} & \text{-5.0190e-001} & \text{-3.3003e-001} & \text{-3.8100e-001} & \text{6.9730e-001} \end{bmatrix}.$$

93.9 Generalized Symmetric Definite Eigenproblems

Definitions:

The **generalized symmetric definite eigenvalue problem (GSEP)** is to find the eigenvalues, λ, and corresponding eigenvectors, $\mathbf{x} \neq 0$, such that

$$A\mathbf{x} = \lambda B\mathbf{x} \quad \text{(type 1)} \tag{93.10}$$

or

$$AB\mathbf{x} = \lambda\mathbf{x} \quad \text{(type 2)} \tag{93.11}$$

or

$$BA\mathbf{x} = \lambda\mathbf{x} \quad \text{(type 3)} \tag{93.12}$$

where A and B are symmetric or Hermitian and B is positive definite.

Background:

For all these problems the eigenvalues λ are real. The matrix Z of the computed eigenvectors satisfies $Z^*AZ = \Lambda$ (problem types 1 and 3) or $Z^{-1}AZ^{-*} = I$ (problem type 2), where Λ is a diagonal matrix with the eigenvalues on the diagonal. Z also satisfies $Z^*BZ = I$ (problem types 1 and 2) or $Z^*B^{-1}Z = I$ (problem type 3). These results are consequences of spectral theory for symmetric matrices. For example, the GSEP type 1 can be rearranged as

$$B^{-\frac{1}{2}}AB^{-\frac{1}{2}}\mathbf{y} = \lambda\mathbf{y},$$

where $\mathbf{y} = B^{\frac{1}{2}}\mathbf{x}$.

Driver Routines:

There are three types of driver routines for solving the GSEP, and each has variations that take advantage of the special structure or storage of the matrices A and B, as shown in the following table:

Types of Matrix (Storage Scheme)	Routine Names Simple Driver	 Divide-and-Conquer	 Expert Driver
General dense	xSYGV/xHEGV	xSYGVD/xHEGVD	xSYGVX/xHEGVX
General dense (packed storage)	xSPGV/xHPGV	xSPGVD/xHPGVD	xSPGVX/xHPGVX
Band matrix	xSBGV/xHBGV	xSBBVD/xHBGVD	xSBGVX/xHBGVX

The simple driver computes all the eigenvalues and (optionally) the eigenvectors. The expert driver computes all or a selected subset of the eigenvalues and (optionally) eigenvectors. The divide-and-conquer driver solves the same problem as the simple driver. It is much faster than the simple driver, but uses more workspace.

Examples:

1. Let us show how to use the simple driver SSYGV to compute the GSEPs (93.10), (93.11), and (93.12). SSGYV first reduces each of these problems to a standard symmetric eigenvalue problem, using a Cholesky decomposition of B, and then computes eigenvalues and eigenvectors of the standard symmetric eigenvalue problem by an implicit QR-type algorithm. SSYGV has the following calling sequence:

   ```
   CALL SSYGV( ITYPE, JOBZ, UPLO, N, A, LDA, B, LDB, W, WORK, LWORK, INFO )
   ```

   Input to `SSYGV`:

`ITYPE`: Specifies the problem type to be solved:

`JOBZ`: = `'N'`, compute eigenvalues only;
= `'V'`, compute eigenvalues and eigenvectors.

`UPLO`: = `'U'`, the upper triangles of A and B are stored;
= `'L'`, the lower triangles of A and B are stored.

`N`: The order of the matrices A and B. $\texttt{N} \geq \texttt{0}$.

`A, LDA`: The symmetric matrix A and the leading dimension of the array `A`. $\texttt{LDA} \geq \max(\texttt{1,N})$.

`B`: The symmetric positive definite matrix B and the leading dimension of the array `B`. $\texttt{LDB} \geq \max(\texttt{1,N})$.

`WORK, LWORK`: The workspace array and its length. $\texttt{LWORK} \geq \max(\texttt{1}, \texttt{3} * \texttt{N} - \texttt{1})$. If $\texttt{LWORK} = -\texttt{1}$, then a workspace query is assumed; the routine only calculates the optimal size of the `WORK` array, and returns this value as the first entry of the `WORK` array.

Output from `SSYGV`:

`A`: Contains the normalized eigenvector matrix Z if requested.

`B`: If $\texttt{INFO} \leq \texttt{N}$, the part of B containing the matrix is overwritten by the triangular factor U or L from the Cholesky factorization $B = U^TU$ or $B = LL^T$.

`W`: The eigenvalues in ascending order.

`WORK`: If $\texttt{INFO} = 0$, `WORK(1)` returns the optimal `LWORK`.

`INFO`: $= 0$, then successful exit. If $\texttt{INFO} = -j$, then the jth argument had an illegal value. If $\texttt{INFO} > 0$, then SSYGV returned an error code:

- $\texttt{INFO} \leq \texttt{N}$: if $\texttt{INFO} = j$, the algorithm failed to converge;
- $\texttt{INFO} > \texttt{N}$: if $\texttt{INFO} = \texttt{N} + j$, for $1 \leq j \leq \texttt{N}$, then the leading minor of order j of B is not positive definite. The factorization of B could not be completed and no eigenvalues or eigenvectors were computed.

Let us show the use of SSYGV to solve the type 1 GSEP (93.10) for the following 5-by-5 matrices A and B:

$$A = \begin{bmatrix} 10 & 2 & 3 & 1 & 1 \\ 2 & 12 & 1 & 2 & 1 \\ 3 & 1 & 11 & 1 & -1 \\ 1 & 2 & 1 & 9 & 1 \\ 1 & 1 & -1 & 1 & 15 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 12 & 1 & -1 & 2 & 1 \\ 1 & 14 & 1 & -1 & 1 \\ -1 & 1 & 16 & -1 & 1 \\ 2 & -1 & -1 & 12 & -1 \\ 1 & 1 & 1 & -1 & 11 \end{bmatrix}.$$

Upon calling SSYGV with $\texttt{N} = \texttt{5}, \texttt{LWORK} = \texttt{3} * \texttt{N} - \texttt{1} = \texttt{14}$, `A` is overwritten by the eigenvector matrix Z:

$$Z = \begin{bmatrix} -0.1345906 & 0.0829197 & -0.1917100 & 0.1420120 & -0.0763867 \\ 0.0612948 & 0.1531484 & 0.1589912 & 0.1424200 & 0.0170980 \\ 0.1579026 & -0.1186037 & -0.0748390 & 0.1209976 & -0.0666645 \\ -0.1094658 & -0.1828130 & 0.1374690 & 0.1255310 & 0.0860480 \\ 0.0414730 & 0.0035617 & -0.0889779 & 0.0076922 & 0.2894334 \end{bmatrix}.$$

The corresponding eigenvalues are returned in `W`:

$$\texttt{W} = \begin{bmatrix} 0.4327872 & 0.6636626 & 0.9438588 & 1.1092844 & 1.4923532 \end{bmatrix}.$$

93.10 Generalized Nonsymmetric Eigenproblems

Definitions:

The **generalized nonsymmetric eigenvalue problem (GNEP)** is to find the eigenvalues, λ, and corresponding (right) eigenvectors, $\mathbf{x} \neq 0$, such that

$$A\mathbf{x} = \lambda B\mathbf{x} \tag{93.13}$$

and, optionally, the corresponding left eigenvectors $\mathbf{y} \neq 0$, such that

$$\mathbf{y}^* A = \lambda \mathbf{y}^* B, \tag{93.14}$$

where A and B are n-by-n matrices. In this section the terms **right eigenvector** and **left eigenvector** are used as just defined.

Background:

Sometimes an equivalent notation is used to refer to the GNEP of the pair (A, B). The GNEP can be solved via the generalized Schur decomposition of the pair (A, B), defined in the real case as

$$A = QSZ^T, \quad B = QTZ^T,$$

where Q and Z are orthogonal matrices, T is upper triangular, and S is an upper quasi-triangular matrix with 1-by-1 and 2-by-2 diagonal blocks, the 2-by-2 blocks corresponding to complex conjugate pairs of eigenvalues. In the complex case, the generalized Schur decomposition is

$$A = QSZ^*, \quad B = QTZ^*,$$

where Q and Z are unitary and S and T are both upper triangular. The columns of Q and Z are called left and right generalized Schur vectors and span pairs of deflating subspaces of A and B. Deflating subspaces are a generalization of invariant subspaces: For each k, $1 \leq k \leq n$, the first k columns of Z span a right deflating subspace mapped by both A and B into a left deflating subspace spanned by the first k columns of Q. It is possible to order the generalized Schur form so that any desired subset of k eigenvalues occupies the k leading position on the diagonal of (S, T). (See Chapter 56 and Chapter 21 for more information on generalized eigenvalue problems.)

Driver Routines:

Both the simple and expert drivers are provided in LAPACK. The simple driver xGGEV computes all eigenvalues of the pair (A, B), and optionally the left and/or right eigenvectors. The expert driver xGGEVX performs the same task as the simple driver routines; in addition, it also balances the matrix pair to try to improve the conditioning of the eigenvalues and eigenvectors, and computes the condition numbers for the eigenvalues and/or left and right eigenvectors.

Examples:

1. Let us show how to use the simple driver SGGEV to solve the GNEPs (93.13) and (93.14). SGGEV first reduces the pair (A, B) to generalized upper Hessenberg form (H, R), where H is upper Hessenberg (zero below the first lower subdiagonal) and R is upper triangular. Then SGGEV computes the generalized Schur form (S, T) of the generalized upper Hessenberg form (H, R), using a QZ algorithm. The eigenvalues are computed from the diagonals of (S, T). Finally, SGGEV computes left and/or right eigenvectors if requested. SGGEV has the following calling sequence:

   ```
   CALL SGGEV( JOBVL, JOBVR, N, A, LDA, B, LDB, ALPHAR, ALPHAI, BETA, VL, LDVL, VR,
   LDVR, WORK, LWORK, INFO )
   ```

   Input to `SGGEV`:

`JOBVL, JOBVR:` `= 'N'`, do not compute the left and/or right eigenvectors;
`= 'V'`, compute the left and/or right eigenvectors.

`N:` The order of the matrices A and B. $\texttt{N} \geq \texttt{0}$.

`A, LDA:` The matrix A and the leading dimension of the array `A`. $\texttt{LDA} \geq \max(\texttt{1,N})$.

`B, LDB:` The matrix B and the leading dimension of the array `B`. $\texttt{LDB} \geq \max(\texttt{1,N})$.

`LDVL, LDVR:` The leading dimensions of the eigenvector matrices `VL` and `VR`. $\texttt{LDVL}, \texttt{LDVR} \geq \texttt{1}$. If eigenvectors are required, then $\texttt{LDVL}, \texttt{LDVR} \geq \texttt{N}$.

`WORK, LWORK:` The workspace array and its length. $\texttt{LWORK} \geq \max(\texttt{1}, \texttt{8} * \texttt{N})$. For good performance, `LWORK` must generally be larger.
If $\texttt{LWORK} = -1$, then a workspace query is assumed; the routine only calculates the optimal size of `WORK`, and returns this value in `WORK(1)` on return.

Output from `SGGEV`:

`ALPHAR, ALPHAI, BETA:` $(\texttt{ALPHAR}(j) + i \cdot \texttt{ALPHAI}(j))/\texttt{BETA}(j)$ for $j = 1, 2, \ldots, \texttt{N}$, are the generalized eigenvalues. If $\texttt{ALPHAI}(j)$ is zero, then the jth eigenvalue is real; if positive, then the jth and $(j+1)$-st eigenvalues are a complex conjugate pair, with $\texttt{ALPHAI}(j+1)$ negative.

`VL:` If `JOBVL = 'V'`, the left eigenvectors $\mathbf{y}_j$ are stored in the columns of `VL`, in the same order as their corresponding eigenvalues. If the jth eigenvalue is real, then $\mathbf{y}_j = \texttt{VL}(:, j)$, the jth column of `VL`. If the jth and $(j+1)$th eigenvalues form a complex conjugate pair, then $\mathbf{y}_j = \texttt{VL}(:, j) + i \cdot \texttt{VL}(:, j+1)$ and $\mathbf{y}_{j+1} = \texttt{VL}(:, j) - i \cdot \texttt{VL}(:, j+1)$.

`VR:` If `JOBVR = 'V'`, the right eigenvectors $\mathbf{x}_j$ are stored one after another in the columns of `VR`, in the same order as their eigenvalues. If the jth eigenvalue is real, then $\mathbf{x}_j = \texttt{VR}(:, j)$, the jth column of `VR`. If the jth and $(j+1)$th eigenvalues form a complex conjugate pair, then $\mathbf{x}_j = \texttt{VR}(:, j) + i \cdot \texttt{VR}(:, j+1)$ and $\mathbf{x}_{j+1} = \texttt{VR}(:, j) - i \cdot \texttt{VR}(:, j+1)$.

`WORK:` If $\texttt{INFO} = 0$, `WORK(1)` returns the optimal `LWORK`.

`INFO:` `INFO = 0` if successful exit. If $\texttt{INFO} = -j$, the jth argument had an illegal value. If `INFO = 1,...,N`, then the QZ iteration failed. No eigenvectors have been calculated, but $\texttt{ALPHAR}(j)$, $\texttt{ALPHAI}(j)$, and $\texttt{BETA}(j)$ should be correct for $j = \texttt{INFO} + 1, \ldots, \texttt{N}$. If `INFO = N+1`, then other than QZ iteration failed in SHGEQZ. If `INFO = N+2`, then error return from STGEVC.

Note that the quotients $\texttt{ALPHAR}(j)/\texttt{BETA}(j)$ and $\texttt{ALPHAI}(j)/\texttt{BETA}(j)$ may easily over- or underflow, and $\texttt{BETA}(j)$ may even be zero. Thus, the user should avoid naively computing the ratio. However, `ALPHAR` and `ALPHAI` will always be less than and usually comparable to $\|A\|$ in magnitude, and `BETA` always less than and usually comparable to $\|B\|$.

Let us demonstrate the use of SGGEV in solving the GNEP of the following 6-by-6 matrices A and B:

$$A = \begin{bmatrix} 50 & -60 & 50 & -27 & 6 & 6 \\ 38 & -28 & 27 & -17 & 5 & 5 \\ 27 & -17 & 27 & -17 & 5 & 5 \\ 27 & -28 & 38 & -17 & 5 & 5 \\ 27 & -28 & 27 & -17 & 16 & 5 \\ 27 & -28 & 27 & -17 & 5 & 16 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 16 & 5 & 5 & 5 & -6 & 5 \\ 5 & 16 & 5 & 5 & -6 & 5 \\ 5 & 5 & 16 & 5 & -6 & 5 \\ 5 & 5 & 5 & 16 & -6 & 5 \\ 5 & 5 & 5 & 5 & -6 & 16 \\ 6 & 6 & 6 & 6 & -5 & 6 \end{bmatrix}.$$

The exact eigenvalues are $\frac{1}{2} + i \cdot \frac{\sqrt{3}}{2}$, $\frac{1}{2} + i \cdot \frac{\sqrt{3}}{2}$, $\frac{1}{2} - i \cdot \frac{\sqrt{3}}{2}$, $\frac{1}{2} - i \cdot \frac{\sqrt{3}}{2}$, ∞, ∞. Upon calling SGGEV with $\texttt{N} = \texttt{6}, \texttt{LWORK} = \texttt{48}$, on exit, arrays `ALPHAR`, `ALPHAI`, and `BETA` are

$$\begin{aligned}\texttt{ALPHAR} &= \begin{bmatrix}-25.7687130 & 6.5193458 & 5.8156629 & 5.8464251 & 5.5058141 & 11.2021322\end{bmatrix},\\ \texttt{ALPHAI} &= \begin{bmatrix}0.0000000 & 11.2832556 & -10.0653677 & 10.1340599 & -9.5436525 & 0.0000000\end{bmatrix},\\ \texttt{BETA} &= \begin{bmatrix}0.0000000 & 13.0169611 & 11.6119413 & 11.7124090 & 11.0300474 & 0.0000000\end{bmatrix}.\end{aligned}$$

Therefore, there are two infinite eigenvalues corresponding to $\texttt{BETA}(1) = \texttt{BETA}(6) = 0$ and four finite eigenvalues $\lambda_j = (\texttt{ALPHAR}(j) + i \cdot \texttt{ALPHAI}(j))/\texttt{BETA}(j)$ for $j = 2, 3, 4, 5$.

$$(\texttt{ALPHAR}(2:5) + i \cdot \texttt{ALPHAI}(2:5))/\texttt{BETA}(2:5) = \begin{bmatrix}0.50083 + i \cdot 0.86681\\ 0.50083 - i \cdot 0.86681\\ 0.49917 + i \cdot 0.86524\\ 0.49917 - i \cdot 0.86524\end{bmatrix}.$$

The left eigenvectors $\mathbf{y}_j$ are stored in `VL`. Since $\texttt{ALPHAI}(1) = \texttt{ALPHAI}(6) = 0$, $\mathbf{y}_1 = \texttt{VL}(:,1)$ and $\mathbf{y}_6 = \texttt{VL}(:,6)$. The second and third eigenvalues form a complex conjugate pair, the $\mathbf{y}_2 = \texttt{VL}(:,2) + i \cdot \texttt{VL}(:,3)$ and $\mathbf{y}_3 = \texttt{VL}(:,2) - i \cdot \texttt{VL}(:,3)$. Similarly, $\mathbf{y}_4 = \texttt{VL}(:,4) + i \cdot \texttt{VL}(:,5)$ and $\mathbf{y}_5 = \texttt{VL}(:,4) + i \cdot \texttt{VL}(:,5)$. If we place all the left eigenvectors in a matrix Y, where $Y = [\mathbf{y}_1, \mathbf{y}_2, \mathbf{y}_3, \mathbf{y}_4, \mathbf{y}_5, \mathbf{y}_6]$, we have $Y =$

$$\begin{bmatrix}-0.1666666 & 0.2632965+i\cdot 0.3214956 & 0.2632965-i\cdot 0.3214956 & -0.4613968+i\cdot 0.1902102 & -0.4613968-i\cdot 0.1902102 & 0.1666667\\ -0.1666666 & -0.2834885-i\cdot 0.7165115 & -0.2834885+i\cdot 0.7165115 & 0.9231794-i\cdot 0.0765849 & 0.9231794+i\cdot 0.0765849 & 0.1666667\\ -0.1666666 & 0.1623165+i\cdot 0.7526108 & 0.1623165-i\cdot 0.7526108 & -0.9240005-i\cdot 0.0759995 & -0.9240005+i\cdot 0.0759995 & 0.1666667\\ -0.1666666 & 0.0396326-i\cdot 0.4130635 & 0.0396326+i\cdot 0.4130635 & 0.4619284+i\cdot 0.1907958 & 0.4619284-i\cdot 0.1907958 & 0.1666666\\ -0.1666671 & -0.0605860+i\cdot 0.0184893 & -0.0605860-i\cdot 0.0184893 & 0.0000969-i\cdot 0.0761408 & 0.0000969+i\cdot 0.0761408 & 0.1666666\\ 1.0000000 & -0.0605855+i\cdot 0.0184900 & -0.0605855-i\cdot 0.0184900 & 0.0000959-i\cdot 0.0761405 & 0.0000959+i\cdot 0.0761405 & -1.0000000\end{bmatrix}.$$

The right eigenvectors can be recovered from `VR` in a way similar to the left eigenvectors. If we place all the right eigenvectors in a matrix X, where $X = [\mathbf{x}_1, \mathbf{x}_2, \mathbf{x}_3, \mathbf{x}_4, \mathbf{x}_5, \mathbf{x}_6]$, we have $X =$

$$\begin{bmatrix}0.1666672 & -0.2039835-i\cdot 0.5848466 & -0.2039835+i\cdot 0.5848466 & 0.5722237-i\cdot 0.0237538 & 0.5722237+i\cdot 0.0237538 & 0.1666672\\ 0.1666664 & -0.7090308-i\cdot 0.2908980 & -0.7090308+i\cdot 0.2908980 & 0.4485306-i\cdot 0.5514694 & 0.4485306+i\cdot 0.5514694 & 0.1666664\\ 0.1666666 & -0.7071815+i\cdot 0.2928185 & -0.7071815-i\cdot 0.2928185 & -0.0709520-i\cdot 0.7082051 & -0.0709520+i\cdot 0.7082051 & 0.1666666\\ 0.1666666 & -0.2013957+i\cdot 0.5829236 & -0.2013957-i\cdot 0.5829236 & -0.4667411-i\cdot 0.3361499 & -0.4667411+i\cdot 0.3361499 & 0.1666666\\ 1.0000000 & -0.2023994+i\cdot 0.0000001 & -0.2023994-i\cdot 0.0000001 & 0.0536732-i\cdot 0.1799536 & 0.0536732+i\cdot 0.1799536 & 1.0000000\\ 0.1666666 & -0.2023991-i\cdot 0.0000002 & -0.2023991+i\cdot 0.0000002 & 0.0536734-i\cdot 0.1799532 & 0.0536734+i\cdot 0.1799532 & 0.1666664\end{bmatrix}.$$

93.11 Generalized Singular Value Decomposition

Definitions:

The **generalized (or quotient) singular value decomposition (GSVD or QSVD)** of an m-by-n matrix A and a p-by-n matrix B is given by the pair of factorizations

$$A = U\Sigma_1 \begin{bmatrix}0 & R\end{bmatrix} Q^T \quad \text{and} \quad B = V\Sigma_2 \begin{bmatrix}0 & R\end{bmatrix} Q^T. \tag{93.15}$$

The matrices in these factorizations have the following properties:

- U is m-by-m, V is p-by-p, Q is n-by-n, and all three matrices are orthogonal. If A and B are complex, these matrices are unitary instead of orthogonal, and Q^T should be replaced by Q^* in the pair of factorizations.
- R is r-by-r, upper triangular and nonsingular. $\begin{bmatrix}0 & R\end{bmatrix}$ is r-by-n (in other words, the 0 is an r-by-$(n-r)$ zero matrix). The integer r is the rank of $\begin{bmatrix}A\\ B\end{bmatrix}$.
- Σ_1 is m-by-r and Σ_2 is p-by-r. Both are real, nonnegative, and diagonal, satisfying $\Sigma_1^T\Sigma_1 + \Sigma_2^T\Sigma_2 = I$. Write $\Sigma_1^T\Sigma_1 = \text{diag}(\alpha_1^2, \ldots, \alpha_r^2)$ and $\Sigma_2^T\Sigma_2 = \text{diag}(\beta_1^2, \ldots, \beta_r^2)$. The ratios α_j/β_j for $j = 1, 2, \ldots, r$ are called the **generalized singular values**.

Σ_1 and Σ_2 have the following detailed structures, depending on whether $m-r \geq 0$ or $m-r<0$.

- In the first case, when $m-r \geq 0$,

$$\Sigma_1 = \begin{array}{cc} & \begin{array}{cc} k & \ell \end{array} \\ \begin{array}{r} k \\ \ell \\ m-k-\ell \end{array} & \begin{pmatrix} I & 0 \\ 0 & C \\ 0 & 0 \end{pmatrix} \end{array} \quad \text{and} \quad \Sigma_2 = \begin{array}{cc} & \begin{array}{cc} k & \ell \end{array} \\ \begin{array}{r} \ell \\ p-\ell \end{array} & \begin{pmatrix} 0 & S \\ 0 & 0 \end{pmatrix} \end{array} . \tag{93.16}$$

  Here $k+\ell=r$, and ℓ is the rank of B. C and S are diagonal matrices satisfying $C^2+S^2=I$, and S is nonsingular. Let c_j and s_j be the diagonal entries of C and S, respectively. Then we have $\alpha_1=\cdots=\alpha_k=1$, $\alpha_{k+j}=c_j$ for $j=1,\ldots,\ell$, $\beta_1=\cdots=\beta_k=0$, and $\beta_{k+j}=s_j$ for $j=1,\ldots,\ell$. Thus, the first k generalized singular values $\alpha_1/\beta_1,\ldots,\alpha_k/\beta_k$ are infinite and the remaining ℓ generalized singular values are finite.

- In the second case, when $m-r<0$,

$$\Sigma_1 = \begin{array}{cc} & \begin{array}{ccc} k & m-k & k+\ell-m \end{array} \\ \begin{array}{r} k \\ m-k \end{array} & \begin{pmatrix} I & 0 & 0 \\ 0 & C & 0 \end{pmatrix} \end{array} \quad \text{and} \quad \Sigma_2 = \begin{array}{cc} & \begin{array}{ccc} k & m-k & k+\ell-m \end{array} \\ \begin{array}{r} m-k \\ k+\ell-m \\ p-\ell \end{array} & \begin{pmatrix} 0 & S & 0 \\ 0 & 0 & I \\ 0 & 0 & 0 \end{pmatrix} \end{array} . \tag{93.17}$$

  Again, $k+\ell=r$, and ℓ is the rank of B. C and S are diagonal matrices satisfying $C^2+S^2=I$, and S is nonsingular. Let c_j and s_j be the diagonal entries of C and S, respectively. Then we have $\alpha_1=\cdots=\alpha_k=1$, $\alpha_{k+j}=c_j$ for $j=1,\ldots,m-k$, $\alpha_{m+1}=\cdots=\alpha_r=0$, and $\beta_1=\cdots=\beta_k=0$, $\beta_{k+j}=s_j$ for $j=1,\ldots,m-k$, $\beta_{m+1}=\cdots=\beta_r=1$. Thus, the first k generalized singular values $\alpha_1/\beta_1,\ldots,\alpha_k/\beta_k$ are infinite, and the remaining ℓ generalized singular values are finite.

Background:

Here are some important special cases of the QSVD. First, when B is square and nonsingular, then $r=n$ and the QSVD of A and B is equivalent to the SVD of AB^{-1}, where the singular values of AB^{-1} are equal to the generalized singular values of A and B:

$$AB^{-1} = (U\Sigma_1 RQ^T)(V\Sigma_2 RQ^T)^{-1} = U(\Sigma_1\Sigma_2^{-1})V^T .$$

Second, if the columns of $\begin{bmatrix} A \\ B \end{bmatrix}$ are orthonormal, then $r=n$, $R=I$, and the QSVD of A and B is equivalent to the CS (Cosine-Sine) decomposition of $\begin{bmatrix} A \\ B \end{bmatrix}$:

$$\begin{bmatrix} A \\ B \end{bmatrix} = \begin{bmatrix} U & 0 \\ 0 & V \end{bmatrix} \begin{bmatrix} \Sigma_1 \\ \Sigma_2 \end{bmatrix} Q^T .$$

Third, the eigenvalues and eigenvectors of the pencil $A^TA-\lambda B^TB$ can be expressed in terms of the QSVD of A and B, namely,

$$X^TA^TAX = \begin{bmatrix} 0 & 0 \\ 0 & \Sigma_1^T\Sigma_1 \end{bmatrix} \quad \text{and} \quad X^TB^TBX = \begin{bmatrix} 0 & 0 \\ 0 & \Sigma_2^T\Sigma_2 \end{bmatrix} ,$$

where $X = Q\begin{bmatrix} I & 0 \\ 0 & R^{-1} \end{bmatrix}$. Therefore, the columns of X are the eigenvectors of $A^TA-\lambda B^TB$, and the "nontrivial" eigenvalues are the squares of the generalized singular values. "Trivial" eigenvalues are those corresponding to the leading $n-r$ columns of X, which span the common null space of A^TA

and B^TB. The "trivial eigenvalues" are not well defined.[1] (See Chapter 21 for more information on generalized singular value problems.)

Driver Routines:

The driver routine xGGSVD computes the GSVD (93.15) of A and B.

Examples:

1. Let us show how to use the driver routine SGGSVD to compute the QSVD (93.15). SGGSVD first reduces the matrices A and B to a pair of triangular matrices, and then uses a Jacobi-like method to compute the QSVD of the triangular pair. SGGSVD has the following calling sequence:

   ```
   CALL SGGSVD( JOBU, JOBV, JOBQ, M, N, P, K, L, A, LDA, B, LDB, ALPHA, BETA, U, LDU,
   V, LDV, Q, LDQ, WORK, IWORK, INFO )
   ```

   Input to `SGGSVD`:

   `JOBU, JOBV, JOBQ: = 'U', 'V', 'Q'`, orthogonal matrices U, V, and Q are computed;
   = `'N'`, these orthogonal matrices are not computed.

   `M, N, P:` The number of rows or columns of the matrices A and B as defined in Eq. (93.15).

   `A, LDA:` The `M`-by-`N` matrix A and the leading dimension of the array `A`. `LDA` $\geq \max(1, \mathtt{M})$.

   `B, LDB:` The `P`-by-`N` matrix B and the leading dimension of the array `B`. `LDB` $\geq \max(1, \mathtt{P})$.

   `LDU, LDV, LDQ:` The leading dimension of the arrays `U`, `V`, and `Q` if the orthogonal matrices U, V, and Q are computed, `LDU` $\geq \max(1, \mathtt{M})$, `LDV` $\geq \max(1, \mathtt{P})$, `LDQ` $\geq \max(1, \mathtt{N})$.

   `WORK:` The real workspace array, dimension $\max(3\mathtt{N}, \mathtt{M}, \mathtt{P}) + \mathtt{N}$.

   `IWORK:` The integer workspace array, dimension `N`.

   Output from `SGGSVD`:

   `K, L:` The dimension of the subblocks described in the definition of GSVD. $\mathtt{K}+\mathtt{L}$ is the effective numerical rank of the matrix $\begin{bmatrix} A \\ B \end{bmatrix}$.

   `A:` The entire triangular matrix `R` is stored in `A(1:K+L,N-K-L+1:N)` if $m - r \geq 0$. Otherwise, the subblock $R(1:m, 1:k+\ell)$ of R are stored in `A(1:M,N-K-L+1:N)`.

   `B:` The subblock $R(m+1:k+\ell, m+1:k+\ell)$ of R are stored in `B(M-K+1:L,N+M-K-L+1:N)` if $m - r < 0$.

   `ALPHA, BETA:` The generalized singular value pairs;
   `ALPHA(1:K) = 1` and `BETA(1:K) = 0`.

   - If `M-K-L` $\geq$ `0`, then $\mathtt{ALPHA}(\mathtt{K}+1:\mathtt{K}+\mathtt{L}) = C$ and $\mathtt{BETA}(\mathtt{K}+1:\mathtt{K}+\mathtt{L}) = S$.
   - If `M-K-L` $<$ `0`, then

   $$\mathtt{ALPHA}(\mathtt{K}+1:\mathtt{M}) = C \quad \text{and} \quad \mathtt{ALPHA}(\mathtt{M}+1:\mathtt{K}+\mathtt{L}) = 0,$$
   $$\mathtt{BETA}(\mathtt{K}+1:\mathtt{M}) = S \quad \text{and} \quad \mathtt{BETA}(\mathtt{M}+1:\mathtt{K}+\mathtt{L}) = 1;$$

---

[1] If we tried to compute the trivial eigenvalues in the same way as the nontrivial ones, that is by taking ratios of the leading $n - r$ diagonal entries of X^TA^TAX and X^TB^TBX, we would get 0/0.

And `ALPHA(K+L+1:N) = 0`, `BETA(K+L+1:N) = 0`.

`U, V, Q`: Contains computed orthogonal matrices U, V, and Q if requested.

`INFO`: `INFO = 0` if successful exit. If `INFO` $= -j$, then the jth argument had an illegal value. If `INFO = 1`, the Jacobi-type procedure failed to converge.

Let us demonstrate the use of SGGSVD in computing the QSVD of the following 6-by-5 matrices A and B:

$$A = \begin{bmatrix} 1 & 2 & 3 & 1 & 5 \\ 0 & 3 & 2 & 0 & 2 \\ 1 & 0 & 2 & 1 & 0 \\ 0 & 2 & 3 & 0 & -1 \\ 1 & 0 & 2 & 1 & 1 \\ 0 & 2 & 1 & 0 & 1 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 1 & -2 & 2 & 1 & 1 \\ 0 & 3 & 0 & 0 & 0 \\ 1 & -2 & 2 & 1 & 1 \\ 0 & 2 & 0 & 0 & 0 \\ 2 & -4 & 4 & 2 & 2 \\ 1 & 3 & 2 & 1 & 1 \end{bmatrix}.$$

Upon calling SGGSVD with $\mathtt{M} = \mathtt{6}, \mathtt{P} = \mathtt{6}, \mathtt{N} = \mathtt{5}, \mathtt{LWORK} = \mathtt{20}$, we have $\mathtt{K} = 2$ and $\mathtt{L} = 2$. The QSVD (93.15) of A and B falls in the first case (93.16) since $\mathtt{M} - \mathtt{K} - \mathtt{L} = 6 - 2 - 2 = 2 > 0$. The arrays `ALPHA` and `BETA` are

$$\mathtt{ALPHA} = \begin{bmatrix} 1.0000000 & 1.0000000 & 0.1537885 & 0.5788464 & 0.0000000 \end{bmatrix},$$
$$\mathtt{BETA} = \begin{bmatrix} 0.0000000 & 0.0000000 & 0.9881038 & 0.8154366 & 0.0000000 \end{bmatrix}.$$

Hence, Σ_1 and Σ_2 have the structure as described in Eq. (93.16), namely,

$$\Sigma_1 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0.1537885 & 0 \\ 0 & 0 & 0 & 0.5788464 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \quad \text{and} \quad \Sigma_2 = \begin{bmatrix} 0 & 0 & 0.9881038 & 0 \\ 0 & 0 & 0 & 0.8154366 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}.$$

The first two generalized singular values are infinite, $\alpha_1/\beta_1 = \alpha_2/\beta_2 = \infty$, and the remaining two generalized singular values are finite, $\alpha_3/\beta_3 = 0.15564$ and $\alpha_4/\beta_4 = 0.70986$. Furthermore, the array `A(1:4,2:5)` contains the 4-by-4 upper triangular matrix R as defined in Eq. (93.15):

$$R = \begin{bmatrix} 3.6016991 & -1.7135643 & -0.2843603 & 1.8104467 \\ 0 & -2.6087811 & -4.2943931 & 5.1107349 \\ 0 & 0 & 6.9692163 & 3.5063875 \\ 0 & 0 & 0 & 7.3144341 \end{bmatrix}.$$

The orthogonal matrices U, V, and Q are returned in the arrays `U`, `V`, and `Q`, respectively:

$$U = \begin{bmatrix} -0.6770154 & -0.4872811 & -0.4034495 & -0.2450049 & -0.2151961 & 0.1873468 \\ -0.0947438 & -0.5723576 & 0.4163284 & 0.1218751 & 0.0785425 & -0.6848933 \\ 0.2098812 & 0.0670342 & 0.2612190 & -0.7393155 & -0.5670457 & -0.1228532 \\ 0.6974092 & -0.5903998 & -0.3678919 & 0.0010751 & -0.0196356 & 0.1712235 \\ 0.0000000 & 0.0000001 & -0.0735656 & -0.6152450 & 0.7822418 & -0.0644937 \\ -0.0473719 & -0.2861788 & 0.6744684 & -0.0019711 & 0.1170180 & 0.6687696 \end{bmatrix},$$

$$V = \begin{bmatrix} -0.3017521 & -0.2581125 & 0.9018297 & -0.0002676 & -0.1695592 & -0.0166328 \\ 0.4354534 & -0.2679386 & 0.1028928 & 0.0704557 & 0.2595005 & -0.8097517 \\ -0.3017520 & -0.2581124 & -0.1784097 & -0.8828155 & -0.0002829 & -0.1764375 \\ 0.2903022 & -0.1786257 & -0.1298870 & -0.0008522 & -0.9259184 & -0.0980879 \\ -0.6035041 & -0.5162248 & -0.3568195 & 0.4625078 & -0.0224125 & -0.1660080 \\ 0.4240036 & -0.7046767 & -0.0097810 & -0.0419325 & 0.2146671 & 0.5250862 \end{bmatrix},$$

$$Q = \begin{bmatrix} -0.7071068 & -0.2073452 & -0.5604916 & -0.0112638 & -0.3777966 \\ 0.0000000 & 0.0000000 & 0.0000000 & 0.9995558 & -0.0298012 \\ 0.0000001 & 0.5853096 & 0.2932303 & -0.0225276 & -0.7555932 \\ 0.7071067 & -0.2073452 & -0.5604916 & -0.0112638 & -0.3777965 \\ -0.0000001 & -0.7559289 & 0.5345224 & -0.0112638 & -0.3777965 \end{bmatrix}.$$

ARPACK is a library of Fortran77 subroutines designed to compute a selected subset of the eigenvalues of a large matrix. It is based upon a limited storage scheme called the implicitly restarted Arnoldi method (IRAM) [Sor92]. This software can solve large-scale non-Hermitian or Hermitian (standard and generalized) eigenvalue problems. The IRA method is described in Chapter 57.

This chapter describes the design and performance features of the eigenvalue software ARPACK and gives a brief discussion of usage. More detailed descriptions are available in the papers [Sor92] and [Sor02] and in the ARPACK Users' Guide [LSY98].

The design goals were robustness, efficiency, and portability. Two very important principles that have helped to achieve these goals are modularity and independence from specific vendor-supplied communication and performance libraries.

In this chapter, multiplication of a vector $\mathbf{x}$ by a scalar λ is denoted by $\mathbf{x}\lambda$ so that the eigenvector–eigenvalue relation is $A\mathbf{x} = \mathbf{x}\lambda$. This convention provides for direct generalizations to the more general invariant subspace relations $AX = XH$, where X is an $n \times k$ matrix and H is a $k \times k$ matrix with $k < n$.

94.1 The ARPACK Software

The ARPACK software has been used on a wide range of applications. P_ARPACK is a parallel extension to the ARPACK library and is targeted for distributed memory message passing systems. Both packages are freely available and can be downloaded at `http://www.caam.rice.edu/software/ARPACK/`.

Features (of ARPACK and P_ARPACK):

1. A reverse communication interface.
2. Computes k eigenvalues that satisfy a user-specified criterion, such as largest real part, largest absolute value, etc.
3. A fixed predetermined storage requirement of $n \cdot \mathcal{O}(k) + \mathcal{O}(k^2)$ words.
4. Driver routines are included as templates for implementing various spectral transformations to enhance convergence and to solve the generalized eigenvalue problem, or the SVD problem.
5. Special consideration is given to the generalized problem $A\mathbf{x} = M\mathbf{x}\lambda$ for singular or ill-conditioned symmetric positive semidefinite M.
6. A Schur basis of dimension k that is numerically orthogonal to working precision is always computed. These are also eigenvectors in the Hermitian case. In the non-Hermitian case eigenvectors are available on request. Eigenvalues are computed to a user-specified accuracy.

94.2 Reverse Communication

Reverse communication is a means to overcome certain restrictions in the Fortran language; with reverse communication, control is returned to the calling program when interaction with the matrix is required. This is a convenient interface for experienced users. However, it may be more challenging for inexperienced users. It has proven to be extremely useful for interfacing with large application codes.

This interface avoids having to express a matrix-vector product through a subroutine with a fixed calling sequence or to provide a sparse matrix with a specific data structure. The user is free to choose any convenient data structure for the matrix representation.

Examples:

1. A typical use of this interface is illustrated as follows:

```
 10  continue
     call snaupd (ido, bmat, n, which,..., workd,..., info)
     if (ido .eq. newprod) then
        call matvec ('A', n, workd(ipntr(1)), workd(ipntr(2)))
     else
        return
     endif
     go to 10
%
```

This shows a code segment of the routine the user must write to set up the reverse communication call to the top level ARPACK routine `snaupd` to solve a nonsymmetric eigenvalue problem in single precision. With reverse communication, control is returned to the calling program when interaction with the matrix A is required. The action requested of the calling program is specified by the reverse communication parameter `ido`, which is set in the call to `snaupd`. In this case, there are two possible requests indicated by `ido`. One action is to multiply the vector held in the array `workd` beginning at location `ipntr(1)` by A and then place the result in the array `workd` beginning at location `ipntr(2)`. The other action is to halt the iteration due to successful convergence or due to an error.

When the parameter `ido` indicates a new matrix vector product is required, a call is made to a subroutine `matvec` in this example. However, it is only necessary to supply the action of the matrix on the specified vector and put the result in the designated location. No specified

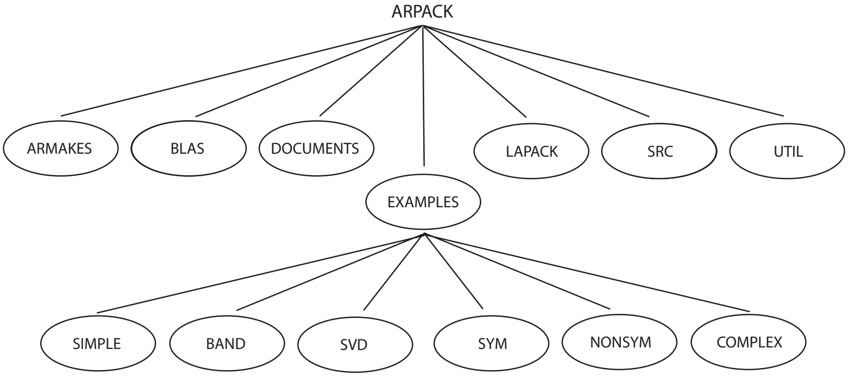

FIGURE 94.1 The ARPACK directory structure.

data structure is imposed on A and if a subroutine is used, no particular calling sequence is specified. Because of this, reverse communication is very flexible and even provides a convenient way to use ARPACK interfaced with code written in another language, such as C or C++.

94.3 Directory Structure and Contents

Once the ARPACK software has been downloaded and unbundled, a directory structure will have been created as pictured in Figure 94.1.

Subdirectories:

1. The `ARMAKES` subdirectory contains sample files with machine-specific information needed during the building of the ARPACK library.
2. The `BLAS` and `LAPACK` subdirectories contain the necessary codes from those libraries.
3. The `DOCUMENTS` subdirectory contains files that have example templates showing how to invoke the different computational modes offered by ARPACK.
4. Example driver programs illustrating all of the computational modes, data types, and precisions may be found in the `EXAMPLES` directory.
5. Programs for banded, complex, nonsymmetric, symmetric eigenvalue problems, and singular value decomposition may be found in the directories `BAND, COMPLEX, NONSYM, SYM, SVD`.
6. The `README` files in each subdirectory provide further information.
7. The `SRC` subdirectory contains all the ARPACK source codes.
8. The `UTIL` subdirectory contains the various utility routines needed for printing results and timing the execution of the ARPACK subroutines.

94.4 Naming Conventions, Precisions, and Types

1. ARPACK has two interface routines that must be invoked by the user. They are `__aupd` that implements the IRAM and `__eupd` to post-process the results of `__aupd.`
2. The user may request an orthogonal basis for a selected invariant subspace or eigenvectors corresponding to selected eigenvalues with `__eupd.` If a spectral transformation is used, `__eupd` automatically transforms the computed eigenvalues of the shift-invert operator to those of the original problem.

3. Both `__aupd` and `__eupd` are available for several combinations of problem type (symmetric and nonsymmetric), data type (real, complex), and precision (single, double). The first letter `(s,d,c,z)` denotes precision and data type. The second letter denotes whether the problem is symmetric (`s`) or nonsymmetric (`n`).
4. Thus, `dnaupd` is the routine to use if the problem is a double precision nonsymmetric (standard or generalized) problem and `dneupd` is the post-processing routine to use in conjunction with `dnaupd` to recover eigenvalues and eigenvectors of the original problem upon convergence. For complex matrices, one should use `_naupd` and `_neupd` with the first letter either `c` or `z` regardless of whether the problem is Hermitian or non-Hermitian.

94.5 Getting Started

Perhaps the easiest way to rapidly become acquainted with the possible uses of ARPACK is to run the example driver routines that have been supplied for each of the computational modes. These may be used as templates and adapted to solve specific problems. To get started, it is recommended that the user execute driver routines from the `SIMPLE` subdirectory.

The `dssimp` driver implements the reverse communication interface to the routine `dsaupd` that will compute a few eigenvalues and eigenvectors of a symmetric matrix. It illustrates the simplest case and has exactly the same structure as shown previously except that the top level routine is `dsaupd` instead of `snaupd`. The full call issued by `dssimp` is as follows.

```
call dsaupd ( ido, bmat, n, which, nev, tol, resid,
&              ncv, v, ldv, iparam, ipntr, workd,
&              workl, lworkl, info )
```

This `dssimp` driver is intended to serve as a template to enable a user to create a program to use `dsaupd` on a specific problem in the simplest computational mode. All of the driver programs in the various `EXAMPLES` subdirectories are intended to be used as templates. They all follow the same principle, but the usage is slightly more complicated.

The only thing that must be supplied in order to use this routine on your problem is to change the array dimensions and to supply a means to compute the matrix-vector product

$$\mathbf{w} \leftarrow A\mathbf{v}$$

on request from `dsaupd`. The selection of which eigenvalues to compute may be altered by changing the parameter `which`.

Once usage of `dsaupd` in the simplest mode is understood, it will be easier to explore the other available options such as solving generalized eigenvalue problems using a shift-invert computational mode.

If the computation is successful, `dsaupd` indicates that convergence has taken place through the parameter `ido`. Then various steps may be taken to recover the results in a useful form. This is done through the subroutine `dseupd` as illustrated below.

```
call dseupd(rvec, howmny, select, d, v, ldv, sigma, bmat,
&             n, which, nev, tol, resid, ncv, v, ldv,
&             iparam, ipntr, workd, workl, lworkl, ierr)
```

Eigenvalues are returned in the first column of the two-dimensional array `d` and the corresponding eigenvectors are returned in the first `NCONV (=IPARAM(5))` columns of the two-dimensional array `v` if requested. Otherwise, an orthogonal basis for the invariant subspace corresponding to the eigenvalues in `d` is returned in `v`.

The input parameters that must be specified are

- The logical variable `rvec` = `.true.` if eigenvectors are requested, `.false.` if only eigenvalues are desired.
- The `character*1` parameter `howmny` that specifies how many eigenvectors are desired.
  `howmny = 'A'`: compute `nev` eigenvectors;
  `howmny = 'S'`: compute some of the eigenvectors,
  specified by the logical array `select`.
- `sigma` should contain the value of the shift used if `iparam(7) = 3,4,5`. It is not referenced if `iparam(7) = 1 or 2`.

When requested, the eigenvectors returned by `dseupd` are normalized to have unit length with respect to the M semi-inner product that was used. Thus, if $M = I$, they will have unit length in the standard 2-norm. In general, a computed eigenvector $\mathbf{x}$ will satisfy $1 = \mathbf{x}^T M\mathbf{x}$.

94.6 Setting Up the Problem

To set up the problem, the user needs to specify the number of eigenvalues to compute which eigenvalues are of interest, the number of basis vectors to use, and whether the problem is standard or generalized. These items are controlled by the following parameters.

Parameters for the top-level ARPACK routines:

`ido` — Reverse communication flag.

`nev` — The number of requested eigenvalues to compute.

`ncv` — The number of Arnoldi basis vectors to use through the course of the computation.

`bmat` — Indicates whether the problem is standard `bmat = 'I'` or generalized (`bmat = 'G'`).

`which` — Specifies which eigenvalues of A are to be computed.

`tol` — Specifies the relative accuracy to which eigenvalues are to be computed.

`iparam` — Specifies the computational mode, number of IRAM iterations, the implicit shift strategy, and outputs various informational parameters upon completion of IRAM.

The value of `ncv` must be at least `nev`+1. The options available for `which` include `'LA'` and `'SA'` for the algebraically largest and smallest eigenvalues, `'LM'` and `'SM'` for the eigenvalues of largest or smallest magnitude, and `'BE'` for the simultaneous computation of the eigenvalues at both ends of the spectrum. For a given problem, some of these options may converge more rapidly than others due to the approximation properties of the IRAM as well as the distribution of the eigenvalues of A. Convergence behavior can be quite different for various settings of the `which` parameter. For example, if the matrix is indefinite then setting `which` = `'SM'` will require interior eigenvalues to be computed and the Arnoldi/Lanczos process may require many steps before these are resolved.

For a given `ncv`, the computational work required is proportional to $\texttt{n} \cdot \texttt{ncv}^2$ FLOPS. Setting `nev` and `ncv` for optimal performance is very much problem dependent. If possible, it is best to avoid setting `nev` in a way that will split clusters of eigenvalues. For example, if the five smallest eigenvalues are positive and on the order of 10^{-4} and the sixth smallest eigenvalue is on the order of 10^{-1}, then it is probably better to ask for `nev` = 5 than for `nev` = 3, even if the three smallest are the only ones of interest.

Setting the optimal value of `ncv` relative to `nev` is not completely understood. As with the choice of `which`, it depends upon the underlying approximation properties of the IRAM as well as the distribution of the eigenvalues of A. As a rule of thumb, $\texttt{ncv} \geq 2 \cdot \texttt{nev}$ is reasonable. There are tradeoffs due to the cost of the user-supplied matrix-vector products and the cost of the implicit restart mechanism and the cost of maintaining the orthogonality of the Arnoldi vectors. If the user-supplied matrix-vector product is relatively cheap, then a smaller value of `ncv` may lead to more user matrix-vector products, but an overall decrease in computation time.

Storage Declarations:

The program is set up so that the setting of the three parameters `maxn, maxnev, maxncv` will automatically declare all of the work space needed to run `dsaupd` on a given problem.

The declarations allow a problem size of `N` $\leq$ `maxn`, computation of `nev` $\leq$ `maxnev` eigenvalues, and using at most `ncv` $\leq$ `maxncv` Arnoldi basis vectors during the IRAM. The user may override the default settings used for the example problem by modifying `maxn`, `maxnev`, and `maxncv` in the following parameter statement in the `dssimp` code.

```
      integer     maxn, maxnev, maxncv, ldv
      parameter  (maxn=256, maxnev=10, maxncv=25, ldv=maxn)
```

These parameters are used in the code segment listed in Figure 94.2 for declaring all of the output and work arrays needed by the ARPACK subroutines `dsaupd` and `dseupd`. These will set the storage values in ARPACK arrays.

```
Double precision
&                 v(ldv,maxncv), workl(maxncv*(maxncv+8)),
&                 workd(3*maxn), d(maxncv,2), resid(maxn),
```

FIGURE 94.2 Storage declarations needed for ARPACK subroutine `dsaupd`.

Stopping Criterion:

The stopping criterion is determined by the user through specification of the parameter `tol`. The default value for `tol` is machine precision ϵ_M. There are several things to consider when setting this parameter. In absence of all other considerations, one should expect a computed eigenvalue λ_c to roughly satisfy

$$|\lambda_c - \lambda_t| \leq \texttt{tol}\|A\|_2,$$

where λ_t is the eigenvalue of A nearest to λ_c. Typically, decreasing the value of `tol` will increase the work required to satisfy the stopping criterion. However, setting `tol` too large may cause eigenvalues to be missed when they are multiple or very tightly clustered. Typically, a fairly small setting of `tol` and a reasonably large setting of `ncv` is required to avoid missing multiple eigenvalues. However, some care must be taken. It is possible to set `tol` so small that convergence never occurs. There may be additional complications when the matrix A is nonnormal or when the eigenvalues of interest are clustered near the origin.

Initial Parameter Settings:

The reverse communication flag is denoted by `ido`. This parameter must be initially set to `0` to signify the first call to `dsaupd`. Various algorithmic modes may be selected through the settings of the entries in the integer array `iparam`. The most important of these is the value of `iparam(7)`, which specifies the computational mode to use.

Setting the Starting Vector:

The parameter `info` should be set to `0` on the initial call to `dsaupd` unless the user wants to supply the starting vector that initializes the IRAM. Normally, this default is a reasonable choice. However, if this eigenvalue calculation is one of a sequence of closely related problems, then convergence may be accelerated if a suitable starting vector is specified. Typical choices in this situation might be to use the final value of the starting vector from the previous eigenvalue calculation (that vector will already be in the first column of `V`) or to construct a starting vector by taking a linear combination of the computed eigenvectors from the previously converged eigenvalue calculation. If the starting vector is to be supplied, then it should be placed in the array `resid` and `info` should be set to `1` on entry to `dsaupd`. On completion, the parameter `info` may contain the value `0` indicating the iteration was successful or it may contain a nonzero value indicating an error or a warning condition. The meaning of a nonzero value returned in `info` may be found in the header comments of the subroutine `dsaupd`.

Trace Debugging Capability:

ARPACK provides a means to trace the progress of the computation as it proceeds. Various levels of output may be specified from no output (`level = 0`) to voluminous (`level = 3`) . A detailed description of trace debugging may be found in [LSY98].

94.7 General Use of ARPACK

The Shift and Invert Spectral Transformation Mode:

The most general problem that may be solved with ARPACK is to compute a few selected eigenvalues and corresponding eigenvectors for

$$A\mathbf{x} = M\mathbf{x}\lambda,$$

where A and M are real or complex $n \times n$ matrices.

The shift and invert spectral transformation is used to enhance convergence to a desired portion of the spectrum. If $(\mathbf{x}, \lambda)$ is an eigen-pair for $(\mathbf{A}, \mathbf{M})$ and $\sigma \neq \lambda$, then

$$(A - \sigma M)^{-1} M\mathbf{x} = \mathbf{x}\nu \quad \text{where} \quad \nu = \frac{1}{\lambda - \sigma},$$

where we are requiring that $A - \sigma M$ is nonsingular. Here it is possible for A or M to be singular, but they cannot have a nonzero null vector in common. This transformation is effective for finding eigenvalues near σ since the `nev` eigenvalues ν_j of $C \equiv (A - \sigma M)^{-1} M$ that are largest in magnitude correspond to the `nev` eigenvalues λ_j of the original problem that are nearest to the shift σ in absolute value. As discussed in Chapter 57, these transformed eigenvalues of largest magnitude are precisely the eigenvalues that are easy to compute with a Krylov method. Once they are found, they may be transformed back to eigenvalues of the original problem.

M **Is Hermitian Positive Definite:**

If M is Hermitian positive definite and well conditioned ($\|M\| \cdot \|M^{-1}\|$ is of modest size), then computing the Cholesky factorization $M = LL^*$ and converting $A\mathbf{x} = M\mathbf{x}\lambda$ into

$$(L^{-1} A L^{-*})\mathbf{y} = \mathbf{y}\lambda, \quad \text{where} \quad L^*\mathbf{x} = \mathbf{y}$$

provides a transformation to a standard eigenvalue problem. In this case, a request for a matrix vector product would be satisfied with the following three steps:

1. Solve $L^*\mathbf{z} = \mathbf{v}$ for $\mathbf{z}$.
2. Matrix-vector multiply $\mathbf{z} \leftarrow A\mathbf{z}$.
3. Solve $L\mathbf{w} = \mathbf{z}$ for $\mathbf{w}$.

Upon convergence, a computed eigenvector $\mathbf{y}$ for $(L^{-1}AL^{-*})$ is converted to an eigenvector $\mathbf{x}$ of the original problem by solving the triangular system $L^{*}\mathbf{x} = \mathbf{y}$. This transformation is most appropriate when A is Hermitian, M is Hermitian positive definite, and extremal eigenvalues are sought. This is because $L^{-1}AL^{-*}$ will be Hermitian when A is the same.

If A is Hermitian positive definite and the smallest eigenvalues are sought, then it would be best to reverse the roles of A and M in the above description and ask for the largest algebraic eigenvalues or those of largest magnitude. Upon convergence, a computed eigenvalue $\hat{\lambda}$ would then be converted to an eigenvalue of the original problem by the relation $\lambda \leftarrow 1/\hat{\lambda}$.

M Is NOT Hermitian Positive Semidefinite:

If neither A nor M is Hermitian positive semidefinite, then a direct transformation to standard form is required. One simple way to obtain a direct transformation to a standard eigenvalue problem $C\mathbf{x} = \mathbf{x}\lambda$ is to multiply on the left by M^{-1}, which results in $C = M^{-1}A$. Of course, one should not perform this transformation explicitly since it will most likely convert a sparse problem into a dense one. If possible, one should obtain a direct factorization of M and when a matrix-vector product involving C is called for, it may be accomplished with the following two steps:

1. Matrix-vector multiply $\mathbf{z} \leftarrow A\mathbf{v}$.
2. Solve: $M\mathbf{w} = \mathbf{z}$.

Several problem-dependent issues may modify this strategy. If M is singular or if one is interested in eigenvalues near a point σ, then a user may choose to work with $C \equiv (A - \sigma M)^{-1}M$ but without using the M-inner products discussed previously. In this case, the user will have to transform the converged eigenvalues ν_j of C to eigenvalues λ_j of the original problem.

94.8 Using the Computational Modes

An extensive set of computational modes has been constructed to implement all of the shift-invert options mentioned previously. The problem set up is similar for all of the available computational modes. A detailed description of the reverse communication loop for the various modes (Shift-Invert for a Real Nonsymmetric Generalized Problem) is available in the users' guide [LSY98]. To use any of the modes listed below, the user is strongly urged to modify one of the driver routine **templates** that reside in the `EXAMPLES` directory.

When to Use a Spectral Transformation:

The first thing to decide is whether the problem will require a spectral transformation. If the problem is generalized ($M \neq I$), then a spectral transformation will be required. Such a transformation will most likely be needed for a standard problem if the desired eigenvalues are in the interior of the spectrum or if they are clustered at the desired part of the spectrum. Once this decision has been made and `OP` has been specified, an efficient means to implement the action of the operator `OP` on a vector must be devised. The expense of applying `OP` to a vector will of course have direct impact on performance.

Shift-invert spectral transformations may be implemented with or without the use of a weighted M-inner product. The relation between the eigenvalues of `OP` and the eigenvalues of the original problem must also be understood in order to make the appropriate specification of `which` in order to recover eigenvalues of interest for the original problem. The user must specify the number of eigenvalues to compute, which eigenvalues are of interest, the number of basis vectors to use, and whether the problem is standard or generalized.

Computational Modes for Real Nonsymmetric Problems:

The following subroutines are used to solve nonsymmetric generalized eigenvalue problems in real arithmetic. These routines are appropriate when A is a general nonsymmetric matrix and M is symmetric and positive semidefinite. The reverse communication interface routine for the nonsymmetric double precision eigenvalue problem is `dnaupd`. The routine is called as shown below. The specification of which `nev` eigenvalues is controlled by the `character*2` argument `which`. The most commonly used options are listed below. There are templates available as indicated for each of these.

```
  call dnaupd (ido, bmat, n, which, nev, tol, resid, ncv, v,
 &             ldv, iparam, ipntr, workd, workl, lworkl, info)
```

There are three different shift-invert modes for nonsymmetric eigenvalue problems. These modes are specified by setting the parameter entry `iparam(7) = mode` where `mode = 1,2,3, or 4`.

In the following list, the specification of `OP` and B are given for the various modes. Also, the `iparam(7)` and `bmat` settings are listed along with the name of the sample driver for the given mode. Sample drivers for the following modes may be found in the `EXAMPLES/NONSYM` subdirectory.

1. Regular mode (`iparam(7) = 1, bmat = 'I'`).
   Use driver `dndrv1`.
   (a) Solve $A\mathbf{x} = \mathbf{x}\lambda$ in regular mode.
   (b) `OP` $= A$ and $B = I$.
2. Shift-invert mode (`iparam(7) = 3, bmat = 'I'`).
   Use driver `dndrv2` with `sigma` a real shift.
   (a) Solve $A\mathbf{x} = \mathbf{x}\lambda$ in shift-invert mode.
   (b) `OP` $= (A - \sigma I)^{-1}$ and $B = I$.
3. Regular inverse mode (`iparam(7) = 2, bmat = 'G'`).
   Use driver `dndrv3`.
   (a) Solve $A\mathbf{x} = M\mathbf{x}\lambda$ in regular inverse mode.
   (b) `OP` $= M^{-1}A$ and $B = M$.
4. Shift-invert mode (`iparam(7) = 3, bmat = 'G'`).
   Use driver `dndrv4` with `sigma` a real shift.
   (a) Solve $A\mathbf{x} = M\mathbf{x}\lambda$ in shift-invert mode.
   (b) `OP` $= (A - \sigma M)^{-1}M$ and $B = M$.

94.9 MATLAB's® EIGS

MATLAB has adopted ARPACK for the computation of a selected subset of the eigenvalues of a large (sparse) matrix. The MATLAB function for this is called `eigs` and it is a MATLAB driver to a mex-file compilation of ARPACK. In fact, a user can directly reference this mex-file as `arpackc`. Exactly the same sort of interfaces discussed above can be written in MATLAB to drive `arpackc`.

However, it is far more convenient just to use the provided `eigs` function. The command `D = eigs(A)` returns a vector of the six eigenvalues of `A` of largest magnitude, while `[V,D] =`

`eigs(A)` returns eigenvectors in `V` and the corresponding (six largest magnitude) eigenvalues on the diagonal of the matrix `D`.

The command `eigs(A,M)` solves the generalized eigenvalue problem `A*V = M*V*D`. Here M must be symmetric (or Hermitian) positive definite and the same size as A. If `M` is nonsymmetric, this can also be handled directly, but the user will have to write and pass a function that will compute the action `w <- inv(A - sigma*M)* M*v` as needed. Of course, a sparse direct factorization of `(A - sigma*M)` should be computed at the outset and reused to accomplish this action.

Other capabilities are easily utilized through `eigs`. The commands `eigs(A,k)` and `eigs(A,M,k)` return the `k` largest magnitude eigenvalues.

The commands `eigs(A,k,sigma)` and `eigs(A,M,k,sigma)` return `k` eigenvalues based on `sigma`, where `sigma` is either a scalar or one of the following strings: `'LM'` or `'SM'` - Largest or Smallest Magnitude

```
For real symmetric problems, SIGMA may also be:
   'LA' or 'SA' - Largest or Smallest Algebraic
   'BE' - Both Ends, one more from high end if K
          is odd
For nonsymmetric and complex problems, SIGMA
may also be:
   'LR' or 'SR' - Largest or Smallest Real part
   'LI' or 'SI' - Largest or Smallest Imaginary
    part
```

If `sigma` is a scalar including 0, `eigs` finds the eigenvalues in the complex plane closest to `sigma`. The required sparse matrix factorizations are done automatically when a scalar is passed.

More control and flexibility can be obtained by using the commands `eigs(A,M,sigma,opts)` and `eigs(A,M,k,sigma,opts)` where `opts` is a `struct`. The fields of the `struct opts` will specify the following options:

```
opts.issym: symmetry of A or A-SIGMA*B
     represented by AFUN [{0} | 1]

opts.isreal: complexity of A or A-SIGMA*B
     represented by AFUN [0 | {1}]

opts.tol: convergence: Ritz estimate
     residual <= tol*NORM(A) [scalar | {eps}]

opts.maxit: maximum number of
     iterations [integer | {300}]

opts.p: number of Lanczos vectors:
     K+1<p<=N [integer | {2K}]

opts.v0: starting vector
     [N-by-1 vector | {randomly generated by ARPACK}]

opts.disp: diagnostic information display
     level [0 | {1} | 2]
```

```
opts.cholB: B is actually its Cholesky
     factor CHOL(B) [{0} | 1]

opts.permB: sparse B is actually
     CHOL(B(permB,permB)) [permB | {1:N}]

opts(AFUN,n) accepts the function AFUN
     instead of a matrix
```

In the above list, the items in square brackets denote the possible settings and the item given in curly brackets $\{\cdot\}$ is the default setting. For example, to set the convergence tolerance to 10^{-3}, one should give the command `opts.tol = .001` .

The function passing mechanism can be used to define a customized spectral transformation as in the example with a nonsymmetric `M`. Arguments may be passed to `AFUN(X,P1,P2,...)` by invoking the command `eigs (AFUN,n,k,sigma,opts,P1,P2,...)`.

Thus, all of the functionality of ARPACK is available through `eigs` and, in many cases, it is much easier to use. Moreover, the sparse matrix direct factorizations and reorderings available in the `sparfun` suite are easily used to implement various desirable spectral transformations. It is highly advisable to run sample problems with the characteristics of a desired very large problem in order to get an idea of the best spectral transformation to use and to get an indication of the expected convergence behavior.

Summary of Software for Linear Algebra Freely Available on the Web

Jack Dongarra
University of Tennessee, Oak Ridge National Laboratory, and University of Manchester

Victor Eijkhout
The University of Texas at Austin

Julien Langou
University of Colorado, Denver

Table 95.1 to Table 95.5 present a list of freely available software for the solution of linear algebra problems. The interest is in software for high-performance computers that is available in "open source" form on the Web for solving problems in numerical linear algebra, specifically dense, sparse direct and iterative systems, and sparse iterative eigenvalue problems.

Additional pointers to software can be found at:
`www.nhse.org/rib/repositories/nhse/catalog/#Numerical_Programs_and_ Routines`.

A survey of Iterative Linear System Solver Packages can be found at:
`www.netlib.org/utk/papers/iterative-survey`.

Glossary

This glossary covers most of the terms defined in Chapters 1 to 64. It does not cover some terminology used within a single chapter (including most of the terminology that is specific to a particular application (Chapters 65 to 87)), nor does it cover most of the terminology used in computer software (Chapters 88 to 95). When two sections are listed, both define the term; usually the first listed chapter is the first instance, the second is the primary chapter dealing with the topic. Definitions in this glossary may not give all details; the reader is advised to consult the chapter/section following the term and definition.

A

abelian (group G): A commutative group, i.e., $ab = ba$ for all $a, b \in G$. **Preliminaries**

absolute (matrix norm): As a vector norm, each member of the family is absolute. **50.3**

absolute (vector norm $\|\cdot\|$): For all vectors $\mathbf{x}$, $\|\,|\mathbf{x}|\,\| = \|\mathbf{x}\|$. **50.1**

absolute algebraic connectivity (of simple graph $G = (V, E)$): $\max \alpha(G_w)$ where the maximum is taken over all nonnegative weights w of the edges of G such that $\sum_{e \in E} w(e) = |E|$. **48.5**

absolute error (in approximation $\hat{\mathbf{z}}$ to $\mathbf{z}$): $\|\mathbf{z} - \hat{\mathbf{z}}\|$. **50.4**

absolute value (of complex number $a + bi$): $\sqrt{a^2 + b^2}$. **Preliminaries**

absolute value (of real matrix A): The nonnegative matrix obtained by taking elementwise absolute values of A's entries. **10.1**

access: Vertex u has access to vertex v in a digraph Γ if there is a walk in Γ from u to v; also applied to sets of vertices. **10.1**, **40.5**

access equivalence class (of a digraph): An equivalence class under the equivalence relation of access. **10.1**, **40.5**

access equivalence class (of a matrix): An access equivalence class of its digraph. **10.1**

access equivalent: Two vertices in a digraph that have access to each other. **10.1**, **40.5**

active branch (at a Type I characteristic vertex of a tree): For some Fiedler vector $\mathbf{y}$ the entries in $\mathbf{y}$ corresponding to the vertices in the branch are nonzero. **48.3**

acyclic (square matrix A): The graph of A has no cycles. **26.3**

additive (map $\phi : F^{m \times n} \to F^{m \times n}$): $\phi(A + B) = \phi(A) + \phi(B)$, for all $A, B \in F^{m \times n}$. **30.4**

additive coset (of subspace W): A subset of vectors the form $\mathbf{v} + W = \{\mathbf{v} + \mathbf{w} : \mathbf{w} \in W\}$. **2.3**

additive D-stable (real square matrix A): $A + D$ is stable for every nonnegative diagonal matrix D. **26.4**

additive inverse eigenvalue problem (AIEP): Given $A \in \mathbb{C}^{n \times n}$ and $\lambda_1, \ldots, \lambda_n \in \mathbb{C}$ find a diagonal matrix $D \in \mathbb{C}^{n \times n}$ such that $\sigma(A + D) = \{\lambda_1, \ldots, \lambda_n\}$. **28.9**

additive preserver: An additive map preserving a certain property. **30.4**

adjacency matrix (of digraph Γ of order n): The $n \times n$ 0, 1-matrix whose i, jth entry is 1 if there is an arc from the ith vertex to the jth vertex and 0 otherwise. **40.2**

adjacency matrix (of graph G of order n): The symmetric $n \times n$ matrix whose i, jth entry is equal to the number of edges between the ith vertex and the jth vertex. **39.3**

adjacency matrix (of weighted graph G of order n): The symmetric $n \times n$ matrix whose i, jth entry is equal to the weight of the edge between the ith vertex and the jth vertex. **47.1**

adjacent (matrices A, B): $\operatorname{rank}(A - B) = 1$. **30.4**

adjacent (vertices u and v in a graph): There exists an edge with endpoints u and v. **39.1**

adjoint (of a matrix): See *Hermitian adjoint.*

adjoint (of linear operator T on an inner product space V): $\langle T(\mathbf{u}), \mathbf{v}\rangle = \langle \mathbf{u}, T^*(\mathbf{v})\rangle$ for all $\mathbf{u}, \mathbf{v} \in V$. **5.3**

adjugate: The transpose of the matrix of cofactors. **4.2**

affine parameterized inverse eigenvalue problem: See Section **28.9**.

AIEP: See *additive inverse eigenvalue problem.*

algebra (associative): A vector space A over a field F with a bilinear *multiplication* $(\mathbf{x}, \mathbf{y}) \mapsto \mathbf{xy}$ from $A \times A$ to A satisfying $(\mathbf{xy})\mathbf{z} = \mathbf{x}(\mathbf{yz})$. **Preliminaries**, **86.1**

algebra (nonassociative): See Section **86.1**.

algebraic connectivity (of a simple graph): The second least Laplacian eigenvalue. **39.4, 48.1**

algebraic multigrid preconditioner: A preconditioner that uses principles similar to those used for PDE problems on grids, when the "grid" for the problem is unknown or nonexistent and only the matrix is available. **54.4**

algebraic multiplicity (of an eigenvalue): The number of times the eigenvalue occurs as a root in the characteristic polynomial of the matrix. **4.4**

algebraic Riccati equation: See *nonsymmetric algebraic Riccati equation, continuous-time algebraic Riccati equation, discrete-time algebraic Riccati equation.*

algorithm: A precise set of instructions to perform a task. **50.7**

allows: If P is a property referring to a real matrix, then a sign pattern A allows P if some real matrix in $Q(A)$ has property P. **42.1**

allows a properly signed nest ($n \times n$ sign pattern A): There exists $B \in Q(A)$ and a permutation matrix P such that $\mathrm{sgn}(\det(P^TBP[\{1, \ldots, k\}])) = (-1)^k$ for $k = 1, \ldots, n$. **42.4**

Alt: the map $\mathrm{Alt}(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k) = \frac{1}{m!}\sum_{\pi\in S_m} \mathrm{sgn}(\pi)\mathbf{v}_{\pi(1)} \otimes \cdots \otimes \mathbf{v}_{\pi(k)}$. **14.6**

alt multiplication: $(\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_p) \wedge (\mathbf{v}_{p+1} \wedge \cdots \wedge \mathbf{v}_{p+q}) = \mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_{p+q}$. **14.7**

alternate path to a single arc (in a digraph): A path of length greater than 1 between vertices i and j such that the arc (i, j) is in the digraph. **49.8**

alternating (bilinear form f): $f(\mathbf{v}, \mathbf{v}) = 0$ for all $\mathbf{v} \in V$. **13.3**

alternating ($n \times n$ matrix A): $a_{ii} = 0,\ i = 1, 2, \ldots, n$ and $a_{ji} = -a_{ij},\ 1 \leq i, j \leq n$. **13.3, 31.4**

alternating (multilinear form): See *antisymmetric.*

alternating (d-tensor T): $\pi(T) = \mathrm{sgn}(\pi)T$ for all permutations $\pi \in S_d$. **15.2**

alternating algebra: See *Grassman algebra.*

alternating product: See *exterior product.*

alternating space: See *Grassman space.*

alternator: See *Alt.*

angle (between two nonzero vectors $\mathbf{u}$ and $\mathbf{v}$ in a real inner product space): The real number θ, $0 \leq \theta \leq \pi$, such that $\langle \mathbf{u}, \mathbf{v}\rangle = \|\mathbf{u}\|\|\mathbf{v}\| \cos\theta$. **5.1**

annihilator: The set of linear functionals that annihilate every vector in the given set. **3.8**

(kth-) antidiagonal (of $n \times n$ matrix A): The elements $a_{i,k-i}, i = \min\{1, k-n\}, \ldots, k-1$ for some k with $2 \leq k \leq 2n$. **22.3**

anti-identity matrix: The $n \times n$ matrix with ones along the main antidiagonal, i.e., $a_{i,n+1-i} = 1$, $i = 1, \ldots, n$ and zeros elsewhere. **22.3**

antisymmetric (bilinear form f): $f(\mathbf{u}, \mathbf{v}) = -f(\mathbf{v}, \mathbf{u})$ for all $\mathbf{u}, \mathbf{v} \in V$. **13.3**

antisymmetric (multilinear form): A multilinear form that is an antisymmetric map. **14.5**

antisymmetric (map $\psi \in L^m(V; U)$): $\psi(\mathbf{v}_{\pi(1)}, \ldots, \mathbf{v}_{\pi(m)}) = \mathrm{sgn}(\pi)\psi(\mathbf{v}_1, \ldots, \mathbf{v}_m)$ for all permutations π. **14.5**

aperiodic (matrix): An irreducible nonnegative matrix of period 1. **10.2**

appending G_2 at vertex v of G_1: Constructing a simple graph from $G_1 \cup G_2$ by adding an edge between v and a vertex of G_2. **48.2**

Arbitrary Precision Approximating (APA) algorithms: See Section **61.4**.

arc: An ordered pair of vertices (part of a directed graph). **40.1**

argument (of a complex number): θ in the form $re^{i\theta}$ with $0 \leq \theta < 2\pi$. **Preliminaries**

Arnoldi factorization (k-step): $AV_k = V_k H_k + \mathbf{f}_k \mathbf{e}_k^*$ where $V_k \in \mathbb{C}^{n\times k}$ has orthonormal columns, $V_k^* \mathbf{f}_k = 0$ and $H_k = V_k^* A V_k$ is a $k \times k$ upper Hessenberg matrix with nonnegative subdiagonal elements. **54.3**, **57.2**

associated undirected graph (of digraph $\Gamma = (V, E)$): The undirected graph with vertex set V, having an edge between vertices u and v if and only if at least one of the arcs (u, v) and (v, u) is in Γ. **40.1**

associates (in a domain): a, b are associates if if $a|b$ and $b|a$. **32.1**

association scheme: A set of graphs $G_0, \ldots, G_d$ on a common vertex set satisfying certain axioms. **39.6**

associative algebra: See *algebra (associative).*

asymmetric (digraph $\Gamma = (V, E)$): $(i, j) \in E$ implies $(j, i) \notin E$ for all distinct $i, j \in V$. **49.1**

augmented matrix (of a system of linear equations): Matrix obtained by adjoining the constant column to the coefficient matrix. **1.4**

automorphism (of a weighted graph): A relabeling of the vertices that preserves the weights. **47.3**

B

backward error (for $\hat{f}(\mathbf{x})$): A vector $\mathbf{e} \in \mathbb{R}^n$ of smallest norm for which $f(\mathbf{x} + \mathbf{e}) = \hat{f}(\mathbf{x})$. **50.8**

backward stable (algorithm): The backward relative error $\mathbf{e}$ exists and is small for all valid input data $\mathbf{x}$ despite rounding and truncation errors in the algorithm. **50.8**

backward stable (eigensolver): Instead of the exact eigenpair $(\lambda, \mathbf{x})$, an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ is computed with a small normwise backward error $\eta(\tilde{\lambda}, \tilde{\mathbf{x}})$. **63.2**

badly conditioned: See *ill-conditioned.*

balanced ($(0,1)$-design matrix W): Every row of $m \times n$ matrix W has exactly $(n + 1)/2$ ones if n is odd; exactly $n/2$ ones or exactly $(n + 2)/2$ ones if n is even. **44.4**

balanced (real or sign pattern vector): It is a zero vector or it has both a positive entry and a negative entry. **42.3**

balanced column signing (of matrix A): A column signing of A in which all the rows are balanced. **42.3**

balanced row signing (of matrix A): A row signing of A in which all the columns are balanced. **42.3**

banded (family of Toeplitz matrices with symbol a): There exists some $m \geq 0$ such that $a_{\pm k} = 0$ for all $k \geq m$. **23.2**

barely L-matrix: An L-matrix that is not an L-matrix if any column is deleted. **42.3**

bases: Plural of *basis.*

basic class (of square nonnegative matrix P): An access equivalence class B of P with $\rho(P[B]) = \rho(P)$. **10.3**

basic reduced digraph (of square nonnegative matrix P): The digraph whose vertex-set is the set of basic classes of P and whose arcs are the pairs (B, B') of distinct basic classes of P for which there exists a simple walk from B to B' in the reduced digraph of P. **10.3**

basic solution (to a least squares problem): A least squares solution with at least $n -$rank A zero components. **52.1**

basic variable: A variable in a system of linear equations whose value is determined by the values of the free variables. **1.4**

basis: A set of vectors that is linearly independent and spans the vector space. **2.2**

BD: See *Bezout domain.*

Bezout domain (BD): A GCCD $\mathbb{D}$ such that for any two elements $a, b \in \mathbb{D}$, $(a, b) = pa+qb$, for some $p, q \in \mathbb{D}$. **32.1**

biacyclic (matrix): A matrix whose sparsity pattern has an acyclic bipartite graph. **59.3**

biadjacency matrix (of bipartite graph G): A matrix with rows indexed by one of the bipartition sets and columns indexed by the other, with the value of the entry being the number of edges between the vertices (or weight of the edge between the vertices). **41.1**

BiCG algorithm: Iterative method for solving a linear system using non-Hermitian Lanczos algorithm; the approximate solution $\mathbf{x}_k$ is chosen so that the residual $\mathbf{r}_k$ is orthogonal to Span$\{\hat{\mathbf{r}}_\mathbf{0}, A^*\hat{\mathbf{r}}_\mathbf{0}, \dots, {A^*}^{k-1}\hat{\mathbf{r}}_\mathbf{0}\}$. **54.3**

BiCGSTAB algorithm: Iterative method for solving a linear system using non-Hermitian Lanczos algorithm with improved stability. **54.3**

biclique (of a graph): A subgraph that is a complete bipartite graph. **41.3**

biclique cover (of graph $G = (V, E)$): A collection of bicliques of G such that each edge of E is in at least one biclique. **41.3**

biclique cover number (of graph G): The smallest k such that there is a cover of G by k bicliques. **41.3**

biclique partition (of $G = (V, E)$): A collection of bicliques of G whose edges partition E. **41.3**

biclique partition number (of graph G): The smallest k such that there is a partition of G into k bicliques. **41.3**

bidual space: The dual of the dual space. **3.8**

big-oh: Function f is $O(g)$ if beyond a certain point $|f|$ is bounded by a multiple of $|g|$. **Preliminaries**

bigraph (of the $m \times n$ matrix A): The simple graph with vertex set $U \cup V$ where $U = \{1, 2, \dots, m\}$ and $V = \{1', 2', \dots, n'\}$, and edge set $\{\{i, j'\} : a_{ij} \neq 0\}$. **41.2**

bilinear form (on vector space V over field F): A map f from $V \times V$ into F that satisfies $f(a\mathbf{u_1}+b\mathbf{u_2}, \mathbf{v}) = af(\mathbf{u_1}, \mathbf{v})+bf(\mathbf{u_2}, \mathbf{v})$ and $f(\mathbf{u}, a\mathbf{v_1}+b\mathbf{v_2}) = af(\mathbf{u}, \mathbf{v_1})+bf(\mathbf{u}, \mathbf{v_2})$. **13.1**

bilinear noncommutative algorithms: See Section **61.2**.

binary matrix: A (0,1)-matrix, i.e., a matrix in which each entry is either 0 or 1. **43.3**

biorthogonal (sets of vectors $\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$ and $\{\mathbf{w}_1, \dots, \mathbf{w}_k\}$ in an inner product space): $\langle \mathbf{v_i}, \mathbf{w_j} \rangle = 0$ if $i \neq j$. **54.3**

biorthonormal: The (columns of) X and Y are biorthonormal if $Y^*X = I$. **20.1**

bipartite (graph G): The vertices of G can be partitioned into disjoint subsets U and V such that each edge of G has the form $\{u, v\}$ where $u \in U$ and $v \in V$. **39.1**, **41.1**

bipartite fill-graph of $n \times n$ matrix A with each diagonal entry nonzero: The simple bipartite graph with vertex set $\{1, 2, \dots, n\} \cup \{1', 2', \dots, n'\}$ with an edge joining i and j' if and only if there exists a path from i to j in the directed graph, $\Gamma(A)$, of A each of whose intermediate vertices has label less than $\min\{i, j\}$. **41.2**

bipartite graph (of sparsity pattern $\mathcal{S}$): The graph with vertices partitioned into row vertices $r_1, \dots, r_m$ and column vertices $c_1, \dots, c_n$, where r_k and r_l are connected if and only if $(k, l) \in \mathcal{S}$. **59.3**

bipartite sign pattern: A sign pattern whose digraph is bipartite. **42.5**

bipartition: The sets into which the vertices of a bipartite graph are partitioned. **41.1**

block (in a 2-design): A subset B_i of X (see *2-design*). **44.2**

block (of a graph or digraph): A maximal nonseparable sub(di)graph. **49.1**

block (of a matrix): An entry of a block matrix, which is a submatrix of the original matrix. **11.1**

block-clique (graph or digraph): Every block is a clique. **49.1**

block diagonal (for a particular block matrix structure): A square block matrix A with all off-diagonal blocks 0. **11.2**

block matrix: A matrix that is partitioned into submatrices with the row indices and column indices partitioned into consecutive subsets sequentially. **11.1**

block lower triangular (matrix A): A^T is block upper triangular. **11.2**

block upper triangular (for a particular block matrix structure): A block matrix having every subdiagonal block 0. **11.2**

(0,1)-Boolean algebra: $\{0,1\}$, with $0+0=0$, $0+1=1=1+0$, $1+1=1$, $0*1=0=1*0$, $0*0=0$, and $1*1=1$. **41.3**

Boolean matrix: A matrix whose entries belong to the Boolean algebra. **41.3**

Boolean rank (of $m \times n$ Boolean matrix A): The minimum k such that there exists an $m \times k$ Boolean matrix B and a $k \times n$ Boolean matrix C such that $A = BC$. **41.3**

border rank (of complex hypermatrix A): Lowest r such that A is the limit of a sequence of rank r hypermatrices **15.4**

Bose–Mesner algebra: The algebra generated by the adjacency matrices of the graphs of an association scheme. **39.6**

bottleneck matrix (of a branch of tree T at vertex v): The inverse of the principal submatrix of the Laplacian matrix corresponding to the vertices of that branch. **48.3**

boundary (of a subset S of $\mathbb{R}$ or $\mathbb{C}$): The intersection of the closure of S and the closure of the complement of S. **Preliminaries**

Bunch–Parlett factorization (of symmetric real matrix H): The factorization $P^THP = LBL^T$, where P is a permutation matrix, B is a block–diagonal matrix with diagonal blocks of sizes 1×1 or 2×2, and L is a full column rank unit lower triangular matrix, where the diagonal blocks in L which correspond to 2×2 blocks in B are 2×2 identity matrices. **21.5**

Businger–Golub pivoting: A particular pivoting strategy for QR-factorization. **59.2**

C

canonical angles (between the column spaces of X, $Y \in \mathbb{C}^{n\times k}$ with $\operatorname{rank} X = \operatorname{rank} Y = k$): $\theta_i = \arccos \sigma_i$, where $\{\sigma_i\}_{i=1}^k$ are the singular values of $(Y^*Y)^{-1/2}Y^*X(X^*X)^{-1/2}$ **21.1**

canonical angle matrix: $\operatorname{diag}(\theta_1, \theta_2, \dots, \theta_k)$, where $\theta_1, \theta_2, \dots, \theta_k$ are the canonical angles. **21.1**

canonical correlations (between subspaces X and Y of $\mathbb{C}^r$): Cosines of principal angles. **24.7**

Cartesian product (of simple graphs $G = (V, E)$ and $G' = (V', E')$): The graph with vertex set $V \times V'$, where two distinct vertices (v, v') and (u, u') are adjacent if and only if (1) $v = u$ and $v'u' \in E(G')$, or (2) $v' = u'$ and $vu \in E(G)$. **46.1**

Cauchy matrix: Given vectors $\mathbf{x} = [x_1, \dots, x_n]^T$ and $\mathbf{y} = [y_1, \dots, y_n]^T$, the Cauchy matrix $C(\mathbf{x}, \mathbf{y})$ has i, j-entry equal to $\frac{1}{x_i - y_j}$. **22.5**

Cauchy-like with displacement rank r (matrix A): A satisfies a displacement equation of the form $D_{\mathbf{v}}A - AD_{\mathbf{w}} = XY^*$ where $X \in \mathbb{C}^{m\times r}$ and $Y \in \mathbb{C}^{n\times r}$. **62.1**

center See *central vertex.*

central (real matrix B): The zero vector is in the convex hull of the columns of B. **42.10**

CG: See *conjugate gradient algorithm.*

CGS algorithm: Iterative method for solving a linear system using non-Hermitian Lanczos algorithm. See Section **54.3**.

change-of-basis matrix (from $\mathcal{B}$ to $\mathcal{C}$): The matrix consisting of the coordinate vectors with respect to basis $\mathcal{C}$ of the basis vectors in $\mathcal{B}$. **2.6**

characteristic equation (of pencil $A - xB$): $\det(xB - A) = 0$. **56.1**

characteristic polynomial (of matrix A): $\det(xI - A)$. **4.4**

characteristic polynomial (of pencil $A - xB$): $\det(xB - A)$. **56.1**

characteristic polynomial (of a graph): The characteristic polynomial of its adjacency matrix. **39.3**

characteristic vector (of a subset of m vertices of a graph): The m-vector whose ith entry is 1 if $i \in X$, and 0 otherwise. **41.3**

characteristic vertex (of tree T): See Section **48.3**.

Cholesky decomposition (of positive-definite matrix A): $A = GG^*$ with $G \in \mathbb{C}^{n\times n}$ lower triangular and having positive diagonal entries. **51.4**

Cholesky factorization: See *Cholesky decomposition.*

chord (of a cycle in a graph): An edge joining two nonconsecutive vertices on the cycle. **41.1**

chordal bipartite graph: Every cycle of length 6 or more has a chord. **41.1**

chordal graph: Every cycle of length 4 or more has a chord. **41.1**

1-chordal: See *block-clique.*

chromatic index (of graph G): The smallest number of classes in a partition of edges of G so that no two edges in the same class meet. **38.6**

chromatic number (of graph G): The smallest number of color classes of any vertex coloring of G (not defined if G has loops). **39.5**

circulant matrix: A Toeplitz matrix in which every row is obtained by a single cyclic shift of the previous row. **22.1**

clique (of a digraph): Every vertex has a loop and for any two distinct vertices u, v, both arcs $(u, v), (v, u)$ are present. **49.1**

clique (of a graph that allows loops but not multiple edges): Every vertex has a loop and for any two distinct vertices u, v, the edge $\{u, v\}$ is present. **49.1**

clique (of a simple graph): A subgraph isomorphic to a complete graph. **39.5**

clique covering (of simple graph G): A set of subgraphs of G, each of which is a clique and such that every edge of G is contained in at least one of these cliques. **46.1**

clique covering number (of simple graph G): The smallest number of cliques in a clique covering of G. **46.1**

clique number (of simple graph G): The largest order of a clique in G. **39.5**

closed cone: A cone that is a closed subset of the vector space. **9.5**, **36.1**

closed under matrix direct sums (class of matrices X): Whenever $A_1, A_2, \ldots, A_k$ are X-matrices, then $A_1 \oplus A_2 \oplus \cdots \oplus A_k$ is an X-matrix. **49.1**

closed under permutation similarity (class of matrices X): Whenever A is an X-matrix and P is a permutation matrix, then $P^T AP$ is an X-matrix. **49.1**

closed under taking principal submatrices: See *hereditary.*

closed walk (in a digraph): A walk in which the first vertex equals the last vertex. **40.1**

4-cockade: A bipartite graph created by adding 4 cycles through edge identification to a 4-cycle. **41.2**

cocktail party graph: The graph obtained by deleting a disjoint edges from the complete graph K_{2a}. **39.2**

coclique (of a graph): An induced subgraph with no edges. **39.5**

co-cover (of a $(0, 1)$-matrix): A collection of 1s such that each line of A contains at least one of the 1s. **38.1**

codomain (of $T\colon V \to W$): The vector space W. **3.1**

coefficient matrix: The matrix of coefficients of a system of linear equations. **1.4**

coefficients (of a linear equation): The scalars that occur multiplied by variables. **1.4**

i, j**-cofactor**: $(-1)^{i+j}$ times the i, j-minor. **4.1**

cograph: See *decomposable (graph).*

co-index (of square nonnegative matrix P): $\max\{\nu_P(\lambda) : \lambda \in \sigma(P), |\lambda| = \rho \text{ and } \lambda \neq \rho\}$. **10.3**

Colin de Verdière (type) parameter: A parameter of a simple graph. **39.5**, **46.5**

color change rule: A rule that changes the color of a vertex from white to black in a simple graph with vertices colored black and white. **46.4**

color class: A coclique in a vertex coloring partition of the vertices of a graph. **39.5**

column: The entries of a matrix lying in a vertical line in the matrix. **1.2**

column equivalent (matrices $A, B \in \mathbb{D}^{m\times n}$): $B = AP$ for some $\mathbb{D}$-invertible P. **32.2**

column signing (of real or sign pattern matrix A): AD where D is a signing. **42.3**

column space: See *range.*

column-stochastic (matrix): A square nonnegative matrix having all column sums equal to 1. **10.4**

column sum vector (of a matrix): The vector of column sums. **38.4**

combinatorial hyperdeterminant (of cubical hypermatrix A): $\det(A) = \frac{1}{n!}\sum_{\pi_1,\ldots,\pi_d\in S_n}\left(\operatorname{sgn}\pi_1\cdots\operatorname{sgn}\pi_d\prod_{i=1}^{n} a_{\pi_1(i)\cdots\pi_d(i)}\right)$. **15.9**

combinatorial Laplacian: See *Laplacian matrix.*

combinatorially orthogonal (sign pattern vectors $\mathbf{x}, \mathbf{y}$): $|\{i \ : \ x_i y_i \neq 0\}| \neq 1$. **42.9**

combinatorially symmetric (partial matrix B): b_{ij} specified implies b_{ji} specified. **49.1**

combinatorially symmetric sign pattern A: $a_{ij} \neq 0$ if and only if $a_{ji} \neq 0$. **42.5**

communicate: See *access equivalent.*

commutator: Matrix $A \in \mathrm{GL}(n, F)$ is a commutator if it can be expressed as $BCB^{-1}C^{-1}$. **31.2**

commute: Matrices or linear operators A, B such that $AB = BA$. **1.2**, **3.2**

companion matrix (of a monic polynomial): Square matrix with ones on the subdiagonal and last column consisting of negatives of the polynomial coefficients **4.4**, **6.5**

comparison matrix (of real square matrix A): Matrix having i, j-entry $-|a_{ij}|$ for $i \neq j$ and i, i-entry $|a_{ii}|$. **26.5**

compatible (generalized sign patterns): The intersection of their qualitative classes is nonempty. **42.1**

complement (of set X in universe S): The elements of S not in X. **Preliminaries**

complement (of binary matrix M): $J - M$ (where J is the all 1s matrix). **43.3**

complement (of simple graph $G = (V, E)$): The simple graph having vertex set V and as edges all unordered pairs from V that are not in E. **39.1**

complement (orthogonal): See *orthogonal complement.*

complementary eigenpairs (of $A \in \mathbb{C}^{n\times n}$): Two eigenpairs (L, X) and (M, Y) for invariant subspaces $\mathcal{X}$ and $\mathcal{Y}$ such that $\mathbb{C}^n = \mathcal{X} \oplus \mathcal{Y}$. **20.1**

complete (bipartite graph): A simple bipartite graph with bipartition $\{U, V\}$ such that each $\{u, v\}$ is an edge (for all $u \in U$, $v \in V$). **39.1**, **41.1**

complete (simple graph): The edge set consists of all unordered pairs of distinct vertices. **39.1**

complete edge subdivision (of a simple graph G): The graph obtained by subdividing each edge of G once. **46.1**

complete orthonormal set: An orthonormal set of vectors whose orthogonal complement is 0. **5.2**

completed max-plus semiring: The set $\mathbb{R} \cup \{\pm\infty\}$ equipped with the addition $(a, b) \mapsto \max(a, b)$ and the multiplication $(a, b) \mapsto a + b$, with the convention that $-\infty + (+\infty) = +\infty + (-\infty) = -\infty$. **35.1**

completely positive (matrix A): $A = CC^T$ for some nonnegative $n \times m$ matrix C. **49.4**

completely reducible (matrix A): There is a permutation matrix P such that $PAP^T = A_1 \oplus A_2 \oplus \cdots \oplus A_k$ where $A_1, A_2, \ldots, A_k$ are irreducible and $k \geq 2$. **38.3**

completion (of a partial matrix): A choice of values for the unspecified entries. **49.1**

X**-completion property** (where X is a type of matrix): Digraph (respectively, graph) G has this property if every partial X-matrix B such that $\mathcal{D}(B) = G$ (respectively, $\mathcal{G}(B) = G$) can be completed to an X-matrix. **49.1**

complex conjugate (of $a + bi \in \mathbb{C}$): $a - bi$. **Preliminaries**

complex sign pattern matrix: A matrix of the form $A = A_1 + iA_2$ for sign patterns A_1 and A_2. **42.12**

complex vector space: A vector space over the field of complex numbers. **1.1**

componentwise backward error (of an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$): $\omega(\tilde{\lambda}, \tilde{\mathbf{x}}) = \min\{\max_{i,j} |e_{ij}| : E = [e_{ij}], (A+E)\tilde{\mathbf{x}} = \tilde{\lambda}\tilde{\mathbf{x}}\}$. **63.2**

component-wise relative backward error of the linear system: See Section **51.1**.

component-wise relative distance (between matrices H and $\tilde{H}$): $\text{reldist}(H, \tilde{H}) = \max\limits_{i,j} \dfrac{|h_{ij} - \tilde{h}_{ij}|}{|h_{ij}|}$, where $0/0 = 0$. **21.4**

composite cycle (in sign pattern A): A product of disjoint simple cycles. **42.1**

$k \times k$**-compound matrix**: A matrix formed from the $k \times k$ minors of a given matrix. **4.2**

condensation digraph: See *reduced digraph.*

condiagonalizable (matrix $A \in \mathbb{C}^{n\times n}$): There is an invertible S such that $S^{-1}A\bar{S}$ is diagonal. **7.4**

condition number (of $\mathbf{z}$ with respect to problem P): $\text{cond}_P(\mathbf{z}) = \lim_{\varepsilon\to 0} \sup\left\{ \left(\frac{\|P(\mathbf{z}+\delta\mathbf{z}) - P(\mathbf{z})\|}{\|P(\mathbf{z})\|}\right) \left(\frac{\|\mathbf{z}\|}{\|\delta\mathbf{z}\|}\right) \,\middle|\, \|\delta\mathbf{z}\| \le \varepsilon \right\}$. **50.4**

condition number (of eigenvalue): See *individual condition number, eigenvalue condition number.*

condition number (of invariant subspace $\mathcal{X}$ of matrix A): $c(\mathcal{X}) = \lim_{\epsilon\to 0} \sup_{||E||_F \le \epsilon} \{\frac{||\Theta(\mathcal{X}, \hat{\mathcal{X}})||_F}{\epsilon} : E \in \mathbb{C}^{n\times n}, \hat{\mathcal{X}}$ invariant subspace of $A + E\}$. **63.4**

condition number (of matrix A for linear systems): $\kappa_\nu(A) = \|A^{-1}\|_\nu \, \|A\|_\nu$. **50.5**, **51.1**

condition number of the linear system: $A\hat{\mathbf{x}} = \mathbf{b}$: $\kappa(A, \hat{\mathbf{x}}) = \|A^{-1}\| \frac{\|\mathbf{b}\|}{\|\hat{\mathbf{x}}\|}$. **51.1**

condition number (of least squares problem $A\mathbf{x} = \mathbf{b}$): $\kappa(A) = \sigma_1/\sigma_p$, where rank $A = p$. **52.6**

condition numbers for polar factors ($A = UP$) in the Frobenius norm: $\text{cond}_F(X) = \lim_{\delta\to 0} \sup_{\|\Delta A\|_F \le \delta} \frac{\|\Delta X\|_F}{\delta}$, for $X = P$ or U. **21.3**

conductance: A parameter of a simple graph. **39.5**

cone: A subset K of a real or complex vector space such that for each $\mathbf{x}, \mathbf{y} \in K, c \ge 0$, $\mathbf{x} + \mathbf{y} \in K$ and $c\mathbf{x} \in K$; in Section 36.1 cone is used to mean proper cone. **9.5**, **36.1**

conformable: See *conformal.*

conformal (partitions of matrices A, B): Partitions of block matrices that allow multiplication via the block structure. **11.1**

congruent (matrices $A, B \in F^{n\times n}$): There is an invertible matrix C such that $B = C^T AC$. **13.1**

***congruent** (matrices $A, B \in \mathbb{C}^{n\times n}$): There is an invertible matrix C such that $B = C^* AC$. **7.2**, **9.3**

φ**-congruent** (matrices $A, B \in F^{n\times n}$ with automorphism φ): There is an invertible matrix C such that $B = C^T A\varphi(C)$. **13.4**

congruence normal (matrix $A \in \mathbb{C}^{n\times n}$): $A\overline{A}$ is normal. **7.3**

coninvolutory (matrix $E \in \mathbb{C}^{n\times n}$): $E\bar{E} = I$. **7.5**

conjugate: See *complex conjugate.*

conjugate gradient (CG) algorithm (to solve $H\mathbf{x} = \mathbf{b}$ for preconditioned Hermitian positive definite matrix H): At each step k, the approximation $\mathbf{x}_k$ of the form $\mathbf{x}_k \in \mathbf{x}_0 + \text{Span}\{\mathbf{r}_0, H\mathbf{r}_0, \ldots, H^{k-1}\mathbf{r}_0\}$ for which the $\sqrt{H}$-norm of the error, $\|\mathbf{e}_k\|_{\sqrt{H}} := \langle \mathbf{e}_k, H\mathbf{e}_k\rangle^{1/2}$, is minimal. **54.2**

conjugate normal (matrix $A \in \mathbb{C}^{n\times n}$): $AA^* = \overline{A^*A}$. **7.3**

conjugate partition (of sequence of positive integers $(u_1, u_2, \ldots, u_n)$): The ith element of the conjugate partition is the number of js such that $u_j \ge i$. **Preliminaries**

connected (graph): A graph with nonempty vertex set such that there exists a walk between any two distinct vertices. **39.1**

connected (digraph): A digraph whose associated undirected graph is connected. **40.1**

connected component (of a graph): A connected (induced) subgraph not properly contained in a connected subgraph. **39.1**

consecutive ones property (of $(0,1)$-matrix A): There exists a permutation matrix P such that PA is a Petrie matrix. **41.2**

consimilar (matrices $A, B \in \mathbb{C}^{n\times n}$): There is an invertible S such that $A = SB\bar{S}^{-1}$. **7.4**

consistent: A system of linear equations that has one or more solutions. **1.4**

k-consistent sign pattern A: Every matrix $B \in Q(A)$ has exactly k real eigenvalues. **42.5**

constant (of a linear equation): The scalar not multiplied by a variable. **1.4**

constant vector: The vector of constants of a system of linear equations. **1.4**

continuous-time algebraic Riccati equation (CARE): A NARE of the form $C + XA + A^*X - XBX = 0$ with $C = C^*$, $B = B^*$ and $D = A^*$. **19.4**

contraction (matrix): A matrix $A \in \mathbb{C}^{n\times n}$ such that $\|A\|_2 \le 1$. **25.6**

contraction (of edge e in graph $G = (V, E)$): The operation that merges the endpoints of e in V, and deletes e from E. **39.2**

contraction product (of hypermatrices): See Section **15.1**.

contriangularizable (matrix $A \in \mathbb{C}^{n\times n}$): There is an invertible S such that $S^{-1}A\bar{S}$ is upper triangular. **7.4**

convergent (square nonnegative matrix P): $\lim_{m\to\infty} P^m = 0$. **10.3**

convergent regular splitting: Square real matrix A has a convergent regular splitting if A has a representation $A = M - N$ such that $N \ge 0$, M invertible with $M^{-1} \ge 0$ and $M^{-1}N$ is convergent. **10.5**

converges geometrically to a with (geometric) rate β (complex sequence $\{a_m\}_{m=0,1,\dots}$): $\{\frac{a_m - a}{\gamma^m} : m = 0, 1, \dots\}$ is bounded for each $\beta < \gamma < 1$. **10.1**

convex (set of vectors): Closed under convex combinations. **Preliminaries**

convex combination (of vectors $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k$): A vector of the form $a_1\mathbf{v}_1 + a_2\mathbf{v}_2 + \cdots + a_k\mathbf{v}_k$ with a_i nonnegative and $\sum a_i = 1$ (vector space is real or complex). **Preliminaries**

convex cone: See *cone.*

convex function: A function $f : S \to \mathbb{R}$ where S is a convex set and for all $a \in \mathbb{R}$ such that $0 < a < 1$ and $\mathbf{x}, \mathbf{y} \in S$, $f(a\mathbf{x} + (1-a)\mathbf{y}) \le af(\mathbf{x}) + (1-a)f(\mathbf{y})$. **Preliminaries**

convex hull (of a set of vectors): The set of all convex combinations of the vectors. **Preliminaries**

convex polytope: The convex hull of a finite set of vectors in $\mathbb{R}^n$. **Preliminaries**

coordinate (part of a vector): In the vector space F^n, one of the entries of a vector. **1.1**

coordinate mapping: The function that maps a vector to its coordinate vector. **2.6**

coordinate representation (of a tensor): The hypermatrix representation of the tensor with respect to specified bases. **15.2**

coordinate vector: The vector of coordinates of a vector relative to an ordered basis. **2.6**

coordinates (of a vector relative to a basis): The scalars that occur when the vector is expressed as a linear combination of the basis vectors. **2.6**

copositive (matrix $A \in \mathbb{R}^{n\times n}$): $\mathbf{x}^TA\mathbf{x} \ge 0$ for all $\mathbf{x} \ge 0$. **49.6**

coprime (elements in a domain): 1 is a greatest common divisor of the elements. **32.1**

corner minor: The determinant of a submatrix in the upper right or lower left corner of a matrix. **29.3**

correlation matrix: A positive semidefinite matrix in which every main diagonal entry is 1. **9.4**

cosine (of a complex square matrix A): The matrix defined by the cosine power series, $\cos(A) = I - \frac{A^2}{2!} + \cdots + \frac{(-1)^k}{(2k)!}A^{2k} + \cdots$. **17.4**

cospectral (graphs): Having the same spectrum. **39.3**

cosquare (of a nonsingular complex matrix A): $(A^{-1})^T A$. **7.3**

***cosquare** (of a nonsingular complex matrix A): $(A^{-1})^* A$. **7.2**

cover (of a $(0,1)$-matrix): A collection of lines that contain all the 1s of the matrix. **38.1**

cubed normal (square complex matrix A): A^3 is normal. **7.2**

cubical hypermatrix: A hypermatrix in $F^{n\times\cdots\times n}$. **15.1**

curve segment (from $\mathbf{x}$ to $\mathbf{y}$): The range of a continuous map ϕ from $[0,1]$ to $\mathbb{R}^n$ with $\phi(0)=\mathbf{x}$ and $\phi(1)=\mathbf{y}$. **39.2**

cut-vertex (of connected simple graph G): A vertex v of G such that $G-v$ is disconnected. **46.1**

(k-)**cycle** (in a graph or digraph): A walk (of length k) with all vertices distinct except the first vertex equals the last vertex. **39.1**, **40.1**

cycle (permutation): A permutation τ that maps a subset to itself cyclically. **Preliminaries**

k**-cycle** (in sign pattern A): A formal product of the form $a_{i_1i_2}a_{i_2i_3}\dots a_{i_ki_1}$, where each of the elements is nonzero and the index set $\{i_1, i_2, \dots, i_k\}$ consists of distinct indices. **42.1**

n**-cycle matrix**: The $n\times n$ matrix with ones along the first subdiagonal and in the 1,n-entry, and zeros elsewhere. **22.1**

n**-cycle pattern**: A sign pattern A where the digraph of A is an n-cycle. **42.5**

cycle-clique (digraph): The induced subdigraph of every cycle is a clique. **49.8**

cycle product: A walk product where the walk is a cycle. **40.3**

cyclic normal form (of matrix A): A matrix in specific form that is permutation similar to A. **40.7**

cyclically real (square ray pattern A): The product of every cycle in A is real. **42.12**

D

$\mathbb{D}$**-invertible**, $\mathbb{D}$**-module**, $\mathbb{D}$**-submodule**: Alphabetized under *invertible, module, submodule.*

D-optimal (design matrix W): $\det W^TW$ is maximal over all (± 1)- (or $(0,1)$-) matrices of the given size. **44.1**

damped least squares solution: The solution to the problem $\left(A^TA+\alpha I\right)\mathbf{x} = A^T\mathbf{b}$, where $\alpha > 0$. **52.8**

data fitting: See Section **52.2**.

data perturbations (for linear system $A\mathbf{x}=\mathbf{b}$): Perturbations of A and/or $\mathbf{b}$. **51.1**

decomposable (graph): A simple graph that can be expressed as a sequence of joins or unions of isolated vertices. **46.1**

decomposable tensor: A tensor of the form $\mathbf{v}_1\otimes\cdots\otimes\mathbf{v}_m$. **14.2**, **15.2**

defective (matrix $A\in F^{n\times n}$): There is an eigenvalue of A (over algebraic closure of F) having geometric multiplicity less than its algebraic multiplicity. **4.4**

deflation: A process of reducing the size of the matrix whose eigenvalue decomposition is to be determined, given that one eigenvector is known. **55.1**

degenerate (bilinear form f on vector space V): Not nondegenerate, i.e., the rank of f less than $\dim V$. **13.1** Also applied to φ-sesquilinear form. **13.4**

degree (of matrix polynomial $P(x)=\sum_{j=0}^{\ell}A_jx^j$): The largest integer m such that $A_m\neq 0$. **18.1**

degree (of polynomial $p(x_1,\dots,x_n)\neq 0$): The largest integer m such that there is a term $cx_1^{m_1}\dots x_n^{m_n}$ with $c\neq 0$ in p having degree m. **32.1**

degree (of term $cx_1^{m_1}\dots x_n^{m_n}$ in polynomial $p(x_1,\dots,x_n)$): The sum of the degrees of the x_i, i.e., $\Sigma_i m_i$. **32.1**

degree (of a vertex v of a graph): The number of times that v occurs as an endpoint of an edge. **39.1**

degree (of a vertex v of a weighted graph): The sum of the weights of edges incident with v. **47.1**

deletion (of edge e from graph $G = (V, E)$): The operation that deletes e from E. **39.2**

deletion (of vertex v from graph $G = (V, E)$): The operation that deletes v from V and all edges with endpoint v from E. **39.2**

depth (of eigenvector $\mathbf{x}$ for eigenvalue λ of A): The natural number h such that $\mathbf{x} \in \text{range}(A - \lambda I)^h - \text{range}(A - \lambda I)^{h+1}$. **6.2**

derogatory (matrix $A \in F^{n\times n}$): Some eigenvalue of A (over algebraic closure of F) has geometric multiplicity greater than 1. **4.4**

2-design with parameters (v, k, λ): A collection of k-element subsets (blocks) B_i of a finite set X with $|X| = v$, such that each 2-element subset of X is contained in exactly λ blocks. **44.1**

(± 1)**-design matrix**: A matrix whose entries are 1 or -1. **44.1**

$(0, 1)$**-design matrix**: A matrix whose entries are 1 or 0. **44.1**

det: See *determinant.*

determinant (det): A scalar-valued function of a square matrix or linear operator, defined inductively, and also given by $\det(A) = \sum_{\pi\in S_n} \text{sgn}\, \pi \prod_{i=1}^n a_{i\pi(i)}$ **4.1**

determinantal region (of complex sign pattern or ray pattern A): $S_A = \{\det(B) \;:\; B \in Q(A)\}$. **42.12**

determined by its spectrum (graph G): Every graph cospectral with G is isomorphic to G. **39.3**

diagonal (of a matrix): *The diagonal* means the *main diagonal*, i.e., the set of diagonal entries of a matrix. **1.2** A diagonal is a collection of n nonzero entries in A no two on the same line. **38.2**

diagonal degree matrix (of a weighted graph): The diagonal matrix whose kth entry is the degree of the kth vertex. **47.1**

diagonal entry: An entry that lies in row k and column k for some k. **1.2**

diagonal matrix: A matrix all of whose off-diagonal entries are zero. **1.2**, **11.2**

diagonal pattern: A square sign pattern all of whose off-diagonal entries are zero. **42.1**

diagonal product (of a matrix): The product of the entries on a diagonal of the matrix. **38.6**

diagonalizable (matrix $A \in F^{n\times n}$): There exist nonsingular matrix $B \in F^{n\times n}$ and diagonal matrix $D \in F^{n\times n}$ such that $A = BDB^{-1}$. **4.4**

diagonally dominant ($n \times n$ complex matrix A): $|a_{ii}| \geq \sum_{j=1, j\neq i}^n |a_{ij}|$ for $i = 1, \ldots, n$. **10.5**

diagonally scaled representation (of symmetric matrix H with positive diagonal entries): A factored representation $H = DAD$ with $D = \text{diag}(\sqrt{h_{11}}, \ldots, \sqrt{h_{nn}})$, $a_{ij} = \dfrac{h_{ij}}{\sqrt{h_{ii}h_{jj}}}$. **21.4**

diagonally scaled totally unimodular (DSTU) (real matrix A): There exist diagonal matrices D_1, D_2 and totally unimodular Z such that $A = D_1 Z D_2$. **59.3**

diagonally stable: See *Lyapunov diagonally stable.*

diameter (of a connected graph): The largest distance that occurs between two vertices. **39.1**

digraph: A directed graph having at most one arc between each ordered pair of vertices (loops permitted). **40.1**

digraph (of $n \times n$ matrix A): The digraph having vertices $\{1, \ldots, n\}$ and having arc (i, j) exactly when $a_{ij} \neq 0$. **10.1**, **40.2**

digraph (of $n \times n$ partial matrix B): The digraph having vertices $V = \{1, \ldots, n\}$ and for each $i, j \in V$, (i, j) is an arc exactly when b_{ij} is specified. **49.1**

dilation: Matrix $A \in \mathbb{C}^{n\times n}$ has a dilation $B \in \mathbb{C}^{m\times m}$ if there is $X \in \mathbb{C}^{m\times n}$ such that $X^*X = I_n$ and $X^*BX = A$. **25.6**

dim: See *dimension.*

dimension (dim) (of a vector space): The number of vectors in a basis for the vector space. **2.2**

dimension (dim) (of a convex polytope): The smallest dimension of an affine space containing it. **38.6**

dimension(s) (of a hypermatrix): The dimensions of a d-hypermatrix $A \in F^{n_1\times\cdots\times n_d}$ are $n_1, \ldots, n_d$ (d is properly called the order of A but sometimes A is loosely referred to as d-dimensional) **15.1**

dimension(s) (of a tensor): The dimensions of a d-tensor $\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_d \in V_1 \otimes \cdots \otimes V_d$ are $\dim V_1, \ldots, \dim V_d$ **15.2**

direct sum (of matrices): A block diagonal matrix with these matrices as the diagonal blocks. **2.4, 11.2**

direct sum (of subspaces): $W_1 + \cdots + W_k$ is direct if $W_i \cap (\sum_{j\neq i} W_j) = \{\mathbf{0}\}$ for all $i = 1, \ldots, k$. **2.3**

direct sum (of vector spaces): See *external direct sum.*

directed bigraph (of the real $m\times n$ matrix A): The directed graph with vertices $1, 2, \ldots, m$, $1', 2', \ldots, n'$, with arc (i, j') if and only if $a_{ij} > 0$, and with arc (j', i) if and only if $a_{ij} < 0$. **41.2**

directed edge: See *arc.*

directed graph: A finite nonempty set of vertices and a finite multiset of arcs, where each arc is an ordered pair of vertices. **40.1**

directed multigraph: A directed graph having more than one arc between at least one pair of vertices. **40.1**

discrete-time algebraic Riccati equation (DARE): A NARE of the form $A^*XA + Q - (C + B^*XA)^*(R + B^*XB)^{-1}(C + B^*XA) - X = 0$ where A is $n\times n$, B, C, Q, and R are $n\times m$, $m\times n$, $n\times n$, and $m\times m$, respectively, with $R = R^*$ and $Q = Q^*$. **19.4**

disjoint (graphs): The vertex sets are disjoint sets. **39.1**

dispersion: See Section **29.3**.

displacement equation: An equation of the form $\Delta(A) = XY^*$ where $A \in \mathbb{C}^{m\times n}$, Δ is a displacement operator, $X \in \mathbb{C}^{m\times r}$, and $Y \in \mathbb{C}^{n\times r}$ with $r = \operatorname{rank}(\Delta(A))$. **62.1**

displacement operator: An operator $\Delta\colon \mathbb{C}^{m\times n} \to \mathbb{C}^{m\times n}$ of the form $\Delta(A) = EAF^* - GAH^*$. **62.1**

displacement rank (of a matrix A with respect to displacement operator Δ): The rank of $\Delta(A)$ **62.1**

distance (between two vectors): The norm of their difference. **5.1**

distance (between two vertices in a graph): The length of a shortest path between the vertices (infinite if no path). **39.1**

distance of $W(A)$ to the origin: $\widetilde{w}(A) = \min\{|\mu| : \mu \in W(A)\}$. **25.1**

distance-regular graph: A connected graph with the property that for every pair of vertices u, v, the number of vertices that have distance i from u and distance j from v depends only on i, j, and the distance between u and v. **39.6**

distance transitive graph: A weighted graph with the property that whenever the distance between vertices x and y equals the distance between z and w, there is an automorphism that maps x to z and y to w. **39.1**

distinguished eigenvalue (of nonnegative square matrix P): An eigenvalue of P that has a semipositive eigenvector. **10.1**

d **divides** a (in a domain $\mathbb{D}$): $a = db$ for some $b \in \mathbb{D}$. **32.1**

divisor (i.e., d is a divisor of a): See *divides.*

domain (ring): An integral domain, i.e., a commutative ring without zero divisors and containing identity 1. **32.1**

domain (of $T\colon V \to W$): The vector space V. **3.1**

dominant eigenvalue: λ_1 where $|\lambda_1| > |\lambda_2| \geq \cdots \geq |\lambda_n|$ are the eigenvalues. **55.1**

dot product: See *standard inner product.*

double echelon form: A special type of real matrix. **29.1**

double precision: Typically, floating-point numbers that have machine epsilon roughly 10^{-16} and precision roughly 16 decimal digits. **50.6**

doubly directed tree: A digraph Γ whose associated undirected graph is a tree and whenever (i, j) is an arc in Γ, (j, i) is also an arc in Γ. **40.1**

doubly negative (matrix): A negative definite matrix having every entry negative. **49.5**

doubly nonnegative (matrix): A positive semidefinite matrix having every entry nonnegative. **49.4**

doubly stochastic (matrix): A square nonnegative matrix having all row and column sums equal to 1. **10.4**

downdating (QR factorization): See Section **52.7**.

downshift matrix: A square matrix with ones on the first subdiagonal and zero elsewhere. **62.1**

Drazin inverse (of matrix $A \in \mathbb{C}^{n\times n}$): A matrix $X \in \mathbb{C}^{n\times n}$ satisfying $A^{k+1}X = A^k, XAX = X$, and $AX = XA$, where $k = \text{index}(A)$. **27.1**

DSTU: See *diagonally scaled totally unimodular.*

ΔTP: See *triangular totally positive.*

dual (of a plane embedding of a simple planar graph): See Section **46.1**.

dual basis: A specific basis for the dual space defined from a given basis for the vector space. **3.8**

dual cone (of cone K): See *dual space of cone.*

dual norm (of vector norm $\|\cdot\|$): $\|\mathbf{y}\|^D = \max_{\mathbf{x}\neq 0} \frac{|\mathbf{y}^*\mathbf{x}|}{\|x\|}$. **50.1**

dual space: The vector space of linear functionals on a given vector space. **3.8**

dual space (of cone K): $K^* = \{\mathbf{y} \in V \mid \langle \mathbf{x}, \mathbf{y}\rangle \geq 0 \quad \forall\ \mathbf{x} \in K\}$. **9.5**, **36.1**

E

ED: See *Euclidean domain.*

ED-RCF basis (for a linear operator): See Section **6.5**.

ED-RCF matrix (over F): A block diagonal matrix of the form $C(h_1^{m_1}) \oplus \cdots \oplus C(h_t^{m_t})$ where each $h_i(x)$ is a monic polynomial that is irreducible over F. **6.5**

EDD: See *elementary divisor domain.*

edge: A pair of vertices, part of a graph. **39.1**

edge cut: Let $G = (V, E)$ be a graph, and let $X, V \setminus X$ be a nontrivial partitioning of V. The set E_X of edges of G that have one end point in X and the other end point in $V \setminus X$ is an edge cut. **48.2**

edge subdivision (of simple graph G): A graph obtained by subdividing an edge of G. **46.1**

effective spectral separation: See *separation.*

efficacy (of a processor): See *speed.*

efficient: One algorithm is more efficient than another, if it accomplishes the same task with a lower cost of computation. **50.7**

eigenbasis (of $A \in \mathbb{C}^{n\times n}$): A matrix having as columns a basis of an invariant subspace of matrix A. **20.1**

eigenpair (of $A \in \mathbb{C}^{n\times n}$): An (eigenvalue, eigenvector) pair. **21.1** A pair (L, X) where X is an eigenbasis (matrix) for invariant subspace $\mathcal{X}$ and $AX = XL$. **20.1**

eigenspace (of eigenvalue λ of A): $\ker(A - \lambda I)$. **4.4**

k-**eigenspace** (of matrix or linear operator A at λ): $\ker(A-\lambda I)^k$. **6.1**

eigentriplet (of $A \in \mathbb{C}^{n\times n}$): A vector-scalar-vector triplet $(\mathbf{y},\lambda,\mathbf{x})$ such that $\mathbf{x} \neq 0$, $\mathbf{y} \neq 0$, and $A\mathbf{x} = \lambda\mathbf{x}$, $\mathbf{y}^*A = \lambda\mathbf{y}^*$. **21.1**

eigenvalue (of matrix or linear operator A): A scalar λ such that there exists a nonzero vector $\mathbf{x}$ such that $A\mathbf{x} = \lambda\mathbf{x}$. **4.4**

eigenvalue (of pencil $A - xB$): $\lambda = \mu/\nu$ where $\nu A\mathbf{v} = \mu B\mathbf{v}$ and $\mathbf{v} \neq \mathbf{0}$ (if $\nu = 0, \lambda = \infty$). **56.1**

eigenvalue (of a graph): An eigenvalue of its adjacency matrix. **39.3**

eigenvalue (of invariant subspace $\mathcal{X}$ of matrix A): An eigenvalue of a Rayleigh quotient L of X, where the columns of X are a basis for $\mathcal{X}$. **20.1**

eigenvalue condition number (of eigenvalue λ of matrix A): $\mathrm{cond}(A,\lambda) = \lim_{\epsilon\to 0}\sup_{||E||\leq\epsilon}\{\frac{|\tilde{\lambda}-\lambda|}{\epsilon} : \tilde{\lambda} \in \sigma(A+E), E \in \mathbb{C}^{n\times n}\}$ (= *individual condition number* for simple eigenvalue using the 2-norm). **63.4**

eigenvalue decomposition (EVD) (of real symmetric matrix A): $A = U\Lambda U^T$, where $U^TU = UU^T = I_n$, $\Lambda = \mathrm{diag}(\lambda_1,\ldots,\lambda_n)$ is a real diagonal matrix of eigenvalues, and the columns of U are eigenvectors. **55.1**

eigenvector (of matrix or linear operator A): A nonzero vector $\mathbf{x}$ such that there exists a scalar λ such that $A\mathbf{x} = \lambda\mathbf{x}$. **4.4**

eigenvector (of the pencil $A - xB$): Nonzero vector $\mathbf{v} \in \mathbb{C}^n$ such that there are scalars μ, $\nu \in \mathbb{C}$, not both zero, such that $\nu A\mathbf{v} = \mu B\mathbf{v}$. **56.1**

elementary bidiagonal matrix: An $n \times n$ real matrix whose main diagonal entries are all equal to one, and there is at most one nonzero off-diagonal entry and this entry must occur on the super- or sub-diagonal. **29.2**

elementary divisor domain (EDD): A GCDD such that for any three elements $a, b, c \in \mathbb{D}$ there exists $p, q, x, y \in \mathbb{D}$ such that $(a, b, c) = (px)a + (py)b + (qy)c$. **32.1**

elementary divisors (of an ED-RCF matrix): The polynomials whose companion matrices are the diagonal blocks. **6.5**

elementary divisors (of matrix or linear operator A): The elementary divisors of an ED-RCF matrix similar to A. **6.5**

elementary divisors rational canonical form (of matrix $A \in F^{n\times n}$): An ED-RCF matrix similar to A. **6.5**

elementary divisors rational canonical form (of a linear operator): See Section **6.5**.

elementary divisors rational canonical form matrix: See *ED-RCF matrix*.

elementary matrix: The result of doing one elementary row operation on the identity matrix. **1.5**

elementary column operation: Column analog of an elementary row operation. **6.6**, **32.2**

elementary row operation (on a matrix over a domain): Add a multiple of one row to another, interchange two rows, or multiply a row by an invertible domain element. **6.6**, **32.2**

elementary row operation (on a matrix over a field): Add a multiple of one row to another, interchange two rows, or multiply a row by a nonzero field element. **1.3**

elementary symmetric function: The sum of all products of n variables taken k at a time. **Preliminaries**

elimination graph: A graph, digraph, or bigraph associated with the principal submatrix that remains to be factored during Gaussian elimination. **53.4**

elimination ordering (for the rows of a matrix): A bijection that specifies the order in which the rows of the matrix are eliminated during Gaussian elimination. **53.5**

elimination sequence: See *elimination ordering.*

embedding (of a graph): A representation of a graph in $\mathbb{R}^n$ where edges intersect only at vertices. **39.2**

embedding (of a submatrix): A full size matrix that contains the submatrix in the appropriate place and zeros elsewhere. **27.1**

empty graph: A graph with no edges. **39.1**

endpoint (of an edge in a graph): One of the two vertices on the edge. **39.1**

energy norm: See *M-norm* (alphabetized under norm).

i, j**-entry**: The scalar in row i and column j in a matrix. **1.2**

entry sign symmetric matrix $A \in \mathbb{R}^{n \times n}$: For all i, j, $a_{ij}a_{ji} > 0$ or $a_{ij} = a_{ji} = 0$. **49.11**

entry weakly sign symmetric matrix $A \in \mathbb{R}^{n \times n}$: For all i, j, $a_{ij}a_{ji} \geq 0$. **49.11**

envelope (of sparse matrix A): The set of indices of the elements between the first and last nonzero elements of every row. **53.5**

equivalence relation: A relation that is reflexive, symmetric, and transitive. **Preliminaries**

equivalent (bilinear forms f, g): There exists an ordered basis $\mathcal{B}$ such that the matrix of g relative to $\mathcal{B}$ is congruent to the matrix of f relative to $\mathcal{B}$. **13.1**

φ**-equivalent** (bilinear forms f, g): There exists an ordered basis $\mathcal{B}$ such that the matrix of g relative to $\mathcal{B}$ is φ-congruent to the matrix of f relative to $\mathcal{B}$. **13.4**

***equivalent** (bilinear forms f, g on a complex vector space): φ-equivalent with $\varphi =$ complex conjugation. **13.5**

equivalent (matrices $A, B \in F^{m \times n}$): $B = QAP$ for some invertible matrices Q, P. **2.4**, **7.1**

equivalent (matrices $A, B \in \mathbb{D}^{m \times n}$): $B = QAP$ for some $\mathbb{D}$-invertible matrices Q, P. **32.2**

equivalent (matrix polynomials): $P(x)$ and $Q(x)$ of the same size are equivalent if $P(x) = E_1(x)Q(x)E_2(x)$ for some unimodular matrix polynomials $E_1(x), E_2(x)$. **18.2**

equivalent: Systems of linear equations that have the same solution set. **1.4**

ergodic class (of stochastic matrix P): A basic class of P. **10.4**

ergodic state: A state in an ergodic class. **10.4**

ergodicity coefficient (of complex matrix A): $\max\{|\lambda| : \lambda \in \sigma(P) \text{ and } |\lambda| \neq \rho(A)\}$. **10.1**

error at step k of an iterative method for solving $A\mathbf{x} = \mathbf{b}$: The difference between the true solution $A^{-1}\mathbf{b}$ and the approximate solution $\mathbf{x}_k$: $\mathbf{e}_k := A^{-1}\mathbf{b} - \mathbf{x}_k$. **54.1**

Euclid's Algorithm: See Section **32.1**.

Euclidean distance (matrix A): There exist vectors $\mathbf{x}_1, \ldots, \mathbf{x}_n \in \mathbb{R}^d$ (for some $d \geq 1$) such that $a_{ij} = \|\mathbf{x}_i - \mathbf{x}_j\|_2$ for all $i, j = 1, \ldots, n$. **49.3**

Euclidean domain (ED): A domain $\mathbb{D}$ with a function $d : \mathbb{D}\backslash\{0\} \to \mathbb{Z}^+$ such that for all nonzero $a, b \in \mathbb{D}$, $d(a) \leq d(ab)$ and there exist $t, r \in \mathbb{D}$ such that $a = tb + r$ where either $r = 0$ or $d(r) < d(b)$. **32.1**

Euclidean norm (of a matrix): See *Frobenius norm.*

Euclidean norm (of a vector): See *2-norm.*

Euclidean space: Finite dimensional real vector space with standard inner product. **5.1**

Euler function (of polynomial $f(x)$ over finite field F): The Euler function $\phi(f(x))$ is the number of monic polynomials over F that are of the same degree as $f(x)$ and relatively prime to $f(x)$. **31.1**

EVD: See *eigenvalue decomposition.*

even (permutation): Can be written as the product of an even number of transpositions. **Preliminaries**

even (cycle in a sign pattern): The length of the simple or composite cycle is even. **42.1**

eventually nonnegative (matrix): There exists a positive integer k_0 such that $A^k \geq 0$ for all $k \geq k_0$. **42.11**

eventually positive (matrix): There exists a positive integer k_0 such that $A^k > 0$ for all $k \geq k_0$. **42.11**

expanders (or family of expanders): An infinite family of graphs with constant degree and isoperimetric number bounded from below. **39.5**

explicit restarting (of the Arnoldi algorithm): A straightforward but inferior way to implement polynomial restarting by explicitly constructing the starting vector $\psi(A)\mathbf{v}$ by applying $\psi(A)$ through a sequence of matrix-vector products. **57.5**

exponent (of floating point number x): e in floating point number $x = \pm\left(\frac{m}{b^{p-1}}\right) b^e$. **50.6**

exponent (of a primitive digraph): The smallest value of k that works in the definition of primitivity. **40.6**

exponent (of primitive matrix A): The exponent of the digraph of A. **40.6**

exponent of matrix multiplication complexity: The infimum of the real numbers w such that there exists an algorithm for multiplying $n \times n$ matrices with $O(n^w)$ arithmetic operations. **61.2**

exponential (of square complex matrix A): The matrix defined by the exponential power series, $e^A = I + A + \frac{A^2}{2!} + \cdots + \frac{A^k}{k!} + \cdots$. **17.2**

extended precision: Floating point numbers that have greater than double precision. **50.6**

extension: Signing $D' = \mathrm{diag}(d'_1, d'_2, \ldots, d'_k)$ is an extension of signing D if $D' \neq D$ and $d'_i = d_i$ whenever $d_i \neq 0$. **42.3**

external direct sum (of vector spaces): The cartesian product of the vector spaces with component-wise operations. **2.3**

exterior power (of a vector space): See *Grassman space.*

exterior product (of vectors $\mathbf{v}_1, \ldots, \mathbf{v}_m$): $\mathbf{v}_1 \wedge \cdots \wedge \mathbf{v}_m = m!\mathrm{Alt}(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k)$. **14.6**

extreme point (of a closed convex set S): A point in S that is not a nontrivial convex combination of other points in S. **Preliminaries**

extreme vector $\mathbf{v}$ of cone K: Either $\mathbf{v}$ is the zero vector or $\mathbf{v}$ is nonzero and the face generated by $\mathbf{v}$ is $\Phi(\mathbf{v}) = \{\lambda \mathbf{v} : \lambda \geq 0\}$. **36.1**

F

face F (of cone K): A subcone of K such that $\mathbf{v} \in F,\ \mathbf{v} \geq^K \mathbf{w} \geq^K 0 \Longrightarrow \mathbf{w} \in F$. **36.1**

face of K generated by $S \subseteq K$: The intersection of all faces of cone K containing S. **36.1**

family of Toeplitz matrices (defined by symbol $a = \sum_{k=-\infty}^{\infty} a_k z^k$): The set $\{T_n\}_{n \geq 1}$ where T_n has constants $a_{1-n}, \ldots, a_{n-1}$. **23.2**

Fiedler vector (of simple graph G): An eigenvector of the Laplacian of G corresponding to the algebraic connectivity. **48.1**

field: A nonempty set with two binary operations, addition and multiplication, satisfying commutativity, associativity, distributivity, and existence of identities and inverses. **Preliminaries**

field of rational functions: The quotient field of the field of polynomials over F. **32.1**

field of values: See *numerical range.*

fill element (in sparse matrix A): An element that is zero in A but becomes nonzero during Gaussian elimination. **53.3**

fill graph (of sparse matrix A): The (graph, digraph, or bigraph) of A, together with all the additional edges corresponding to the fill elements that occur during Gaussian elimination. **41.2**, **53.5**

fill matrix (of Gaussian elimination on a matrix): The matrix $M_1 + M_2 + \cdots + M_{n-1} - (n-1)I + U$, where the M_i are Gauss transformations used in the elimination and U is the resulting upper triangular matrix. **53.3**

final (subset α of vertices): No vertex in α has access to a vertex not in α. **10.1**

finite dimensional (vector space V): V has a basis containing a finite number of vectors. **2.2**

finitely generated (ideal I of a domain $\mathbb{D}$): An ideal of $\mathbb{D}$ that is finitely generated as a $\mathbb{D}$-module. **32.1**

finitely generated (module $\mathbf{M}$ over a domain $\mathbb{D}$): There exist k elements (*generators*) $\mathbf{v}_1, \ldots, \mathbf{v}_k \in \mathbf{M}$ so that every $\mathbf{v} \in \mathbf{M}$ is a linear combination of $\mathbf{v}_1, \ldots, \mathbf{v}_k$ over $\mathbb{D}$. **32.3**

fixed space: The set of vectors fixed by a linear transformation. **3.6**

flattening (of a hypermatrix): A matrix made from a hypermatrix by converting the slices to vectors. **15.7**

flip map: See Section **30.2**.

floating point addition, subtraction multiplication, division: Operations on floating point numbers. **50.6**

floating point number: A real number of the form $x = \pm\left(\frac{m}{b^{p-1}}\right) b^e$. **50.6**

floating point operation: One of floating point addition, subtraction, multiplication, division. **50.6**

flop: A floating point operation. **50.7**

FOM: See *full orthogonalization method.*

forest: A graph with no cycles. **39.1**

forward error (in $\hat{f}(\mathbf{x})$): $f(\mathbf{x}) - \hat{f}(\mathbf{x})$, the difference between the mathematically exact function evaluation and the perturbed function evaluation. **50.8**

forward stable (algorithm): The forward relative error is small for all valid input data $\mathbf{x}$ despite rounding and truncation errors in the algorithm. **50.8**

Fourier matrix: $F_n := \frac{1}{\sqrt{n}}\left[\omega_n^{(i-1)(j-1)}\right]_{i,j=1}^{n}$. **22.1**

Frechet derivative: Let $f(X)$ be a mapping of $\mathcal{X} \subset \mathbb{C}^{m\times n}$ to $\mathbb{C}^{k\times \ell}$. If for some $X_0 \in \mathcal{X}$ there is a linear operator $f'(X)$ such that for all sufficiently small E, $f(X_0 + E) = f(X_0) + f'(X_0)E + o(\|E\|)$, then $f'(X_0)$ is the Frechet derivative of f at X_0. **20.3**

free variable: A variable x_i in the solution to a system of linear equations that is a free parameter. **1.4**

Frobenius norm (of $m \times n$ complex matrix A): $\|A\|_F = \sqrt{\sum_{i=1}^{m}\sum_{j=1}^{n}|a_{ij}|^2}$. **8.1**, **50.3**

Frobenius normal form (of matrix A): A block upper triangular matrix with irreducible diagonal blocks that is permutation similar to A. **38.3**

full (cone): Has a nonempty interior. **9.5**, **36.1**

fully indecomposable ($(0,1)$-matrix): Not partly decomposable. **38.2**

full orthogonalization method (FOM): Generates, at each step k, the approximation $\mathbf{x}_k$ of the form $\mathbf{x}_k \in \mathbf{x}_0 + \mathrm{Span}\{\mathbf{r}_0, A\mathbf{r}_0, \dots, A^{k-1}\mathbf{r}_0\}$ for which the residual is orthogonal to the Krylov space. **54.3**

fundamental subspaces (of least squares problem $A\mathbf{x} = \mathbf{b}$): $\mathrm{range}\,A, \ker A^T, \ker A$ and $\mathrm{range}\,A^T$. **52.3**

G

Galerkin condition: The defining condition for a Ritz vector and Ritz value. **57.1**

Gauss multipliers: The nonzero entries in a Gauss vector. **51.3**

Gauss transformation: The matrix $M_k = I - \ell_k \mathbf{e}_k^T$, where ℓ_k is a Gauss vector. **51.3**

Gauss vector: A vector $\ell_k \in \mathbb{C}^n$ with the leading k entries equal to zero. **51.3**

Gauss–Jordan elimination: A process used to find the reduced row echelon form of a matrix. **1.3**

Gaussian elimination: A process used to find a row echelon form of a matrix. **1.3**, **51.3**

g.c.d.: See *greatest common divisor.*

GCDD: See *greatest common divisor domain.*

general displacement equation: See *displacement equation.*

general displacement operator: See *displacement operator.*

geometric hyperdeterminant (of hypermatrix A): A homogeneous polynomial in the entries of A such that $\mathrm{Det}_{n_1,\dots,n_d}(A) = 0$ if and only if the system of multilinear equations $\nabla A(\mathbf{x}_1, \dots, \mathbf{x}_d) = 0$ has a nontrivial solution. **15.9**

general linear group (of order n over F): The multiplicative group consisting of all invertible $n \times n$ matrices over the field F. **31.2**, **84.1**

general solution: A formula that describes every vector in the solution set to a system of linear equations. **1.4**

generalized cycle (in a digraph): A disjoint union of one or more cycles such that every vertex lies on exactly one cycle. **40.1**

generalized cycle product: A walk product where the walk is a generalized cycle. **40.4**

generalized diagonal (of square matrix A): Entries of A corresponding to a generalized cycle in the digraph of A. **40.4**

generalized eigenspace (of matrix or linear operator A at λ): $\ker(A - \lambda I)^{\nu}$, where ν is the index of A at λ. **6.1**

generalized eigenvector (of a matrix or linear operator): A nonzero vector in the generalized eigenspace. **6.1**

generalized Laplacian (of simple graph G): A matrix M such that for $i \neq j$, $m_{ij} < 0$ if the ith and jth vertices are adjacent and $m_{ij} = 0$ otherwise (no restriction for $i = j$). **39.4**

generalized line graph: See Section **39.2**.

generalized Lyapunov (matrix) equation: A linear matrix equation of the form $AXB^* + BXA^* - Q = 0$ where $A, B, Q, X \in \mathbb{C}^{m \times m}$ and $Q = Q^*$. **19.2**

generalized minimal residual (GMRES): Algorithm generates, at each step k, the approximation $\mathbf{x}_k$ of the form $\mathbf{x}_k \in \mathbf{x}_0 + \text{Span}\{\mathbf{r}_0, A\mathbf{r}_0, \dots, A^{k-1}\mathbf{r}_0\}$ for which the 2-norm of the residual is minimal. **54.3**

generalized Schur complement: A matrix defined from a partitioned matrix. **12.6**

generalized sign pattern: A matrix whose entries are from the set $\{+, -, 0, \#\}$, where $\#$ indicates an ambiguous sum (the result of adding $+$ with $-$). **42.1**

generalized Sylvester (matrix) equation: A linear matrix equation of the form $A_1XB_1 + A_2XB_2 - Q = 0$. **19.2**

generators (of an ideal): See *finitely generated.*

generators (of a matrix A relative to a displacement equation $\Delta(A) = XY^*$): The matrices X and Y. **62.1**

generic matrix: A matrix whose nonzero elements are independent indeterminates over the field F. **41.2**

generic rank (of space of hypermatrices $\mathbb{C}^{n_1 \times \cdots \times n_d}$): Maximum of the border ranks of the hypermatrices in $\mathbb{C}^{n_1 \times \cdots \times n_d}$. **15.5**

geometric multiplicity: The dimension of the eigenspace. **4.4**

Geršgorin discs (of $A \in \mathbb{C}^{n \times n}$): $\{z \in \mathbb{C} \ : \ |z - a_{ii}| \leq \sum_{j \neq i} |a_{ij}|\}$ for $i = 1, \dots, n$. **16.2**

girth (of simple graph G): The length of the shortest cycle in G (if G has a cycle); the girth of an acyclic graph is infinite. **46.1**

girth (of set of vectors S): The smallest s so that there is a set of s linearly dependent vectors in S. **15.6**

Givens matrix: See *Givens transformation.*

Givens rotation: See *Givens transformation.*

Givens transformation: An identity matrix modified so that the (i,i) and (j,j) entries are replaced by $c = \cos(\theta)$, the (i,j) entry is replaced by $s = e^{\imath\vartheta}\sin(\theta)$, and the (j,i) entry is replaced by $-\bar{s} = -e^{-\imath\vartheta}\sin(\theta)$. **51.5**

GMRES: See *generalized minimal residual, restarted GMRES algorithm.*

Godsil McKay switching: A method to construct another simple graph from a given simple graph. **47.3**

graded (associative algebra A): There exist $(A_k)_{k \in \mathbb{N}}$ vector subspaces of A such that $A = \bigoplus_{k \in \mathbb{N}} A_k$ and $A_iA_j \subseteq A_{i+j}$ for every $i, j \in \mathbb{N}$. **14.9**

grade (of matrix polynomial $P(x) = \sum_{j=0}^{\ell} A_j x^j$): The highest listed power ℓ of the variable, regardless of whether the coefficient is nonzero. **18.1**

graded matrix $A \in \mathbb{C}^{m \times n}$: A can be scaled as $A = GS$ (or $A = S^*GS$, depending on situation) such that G is "well-behaved" (i.e., $\kappa_2(G)$ is of modest magnitude), where S is a scaling matrix (often diagonal). **21.3**

Gram matrix (of vectors $\mathbf{v}_1, \ldots, \mathbf{v}_n$ in a complex inner product space): The matrix whose i, j-entry is $\langle \mathbf{v}_i, \mathbf{v}_j \rangle$. **9.1**

graph: A finite set of vertices and a finite multiset of edges, where each edge is an unordered pair of vertices (not necessarily distinct). **39.1**

graph (of combinatorially symmetric $n \times n$ partial matrix B): The graph having vertices $V = \{1, \ldots, n\}$ and for each $i, j \in V$, $\{i, j\}$ is an edge exactly when b_{ij} is specified (loops permitted, no multiple edges). **49.1**

graph (of combinatorially symmetric $n \times n$ sign pattern $A = [a_{ij}]$): The graph with vertex set $\{1, 2, \ldots, n\}$ where $\{i, j\}$ is an edge if and only if $a_{ij} \neq 0$ (loops permitted, no multiple edges). **42.1**

graph (of convex polytope $\mathcal{P}$): Vertices are the extreme points of $\mathcal{P}$ and edges are the pairs of extreme points of 1-dimensional faces of $\mathcal{P}$. **38.6**

graph (of $n \times n$ matrix A): The simple graph whose vertex set is $\{1, \ldots, n\}$ and having an edge between vertices i and j $(i \neq j)$ if and only if $a_{ij} \neq 0$ or $a_{ji} \neq 0$. **26.3**, **46.1**

Grassman algebra (on vector space V): $\bigwedge V = \bigoplus_{k \in \mathbb{N}} \left(\bigwedge^k V \right)$ with alt multiplication. **14.9**

Grassmann space (of vector space V): $\bigwedge^m V = \text{Alt}(\bigotimes^m V)$. **14.6**

greatest common divisor (g.c.d.) (of $a_1, \ldots, a_n \in \mathbb{D}$): $d \in \mathbb{D}$ such that $d | a_i$ for $i = 1, ..., n$, and if $d' | a_i, i = 1, ..., n$, then $d' | d$. **32.1**

greatest common divisor domain (GCDD): A domain in which any two elements have a greatest common divisor. **32.1**

greatest integer (of real number x): The greatest integer less than or equal to x. **Preliminaries**

group: A set with one binary operation, satisfying associativity, existence of identity, and inverses. **Preliminaries**

group inverse (of matrix A): A matrix $X \in \mathbb{C}^{n \times n}$ satisfying $AXA = A, XAX = X$, and $AX = XA$. **10.1, 27.1**

group invertible (matrix): A matrix that has a group inverse. **27.1**

H

H-matrix (real square matrix A): The comparison matrix of A is an M-matrix. **26.5**

Hadamard matrix: A ±1-matrix H_n with $H_n H_n^T = nI_n$. **44.2**

Hadamard product (of $A, B \in F^{n \times n}$): The $n \times n$ matrix whose i, j-entry is $a_{ij} b_{ij}$. **9.5**

Hall matrix: An $n \times n$ $(0, 1)$-matrix that does not have a $p \times q$ zero submatrix for positive integers p, q with $p + q > n$. **38.2**

Hamilton cycle: A cycle in a graph that includes all vertices. **39.1**

Hamilton path: A path in a simple graph that includes all vertices. **46.1**

Hamiltonian (matrix): A matrix $H \in \mathbb{R}^{2n \times 2n}$ with $H\mathrm{J} = (H\mathrm{J})^T$ where $\mathrm{J} = \left[\begin{smallmatrix} 0 & I \\ -I & 0 \end{smallmatrix}\right]$. **63.1**

Hamiltonian cycle: See *Hamilton cycle.*

Hankel matrix: A matrix with constant elements along its antidiagonals. **22.3**

Hankel Bezoutian: A matrix A such that $R_n A$ is Toeplitz Bezoutian, where R_n is the anti-identity matrix (need not be Hankel). **22.3**

Hankel-like with displacement rank r (matrix A): A satisfies a displacement equation of the form $Z_m A - A Z_n^* = XY^*$ where $X \in \mathbb{C}^{m \times r}$ and $Y \in \mathbb{C}^{n \times r}$. **62.1**

height (of basic class B): The largest number of vertices on a simple walk that ends at B in the basic reduced digraph. **10.3**

hereditary (class of matrices X): Whenever A is an X-matrix and $\alpha \subseteq \{1, \ldots, n\}$, then $A[\alpha]$ is an X-matrix. **49.1**

Hermite normal form: A generalization of reduced row echelon form used in domains. **32.2**

Hermitian (linear operator on an inner product space): An operator that is equal to its adjoint. **5.3**

Hermitian (matrix): A real or complex matrix equal to its conjugate transpose. **1.2**, **8.2**, **9.1**

Hermitian adjoint (of a matrix): The conjugate transpose of a real or complex matrix. **1.2**

Hermitian form f (on complex vector space V): A sesquilinear form such that $f(\mathbf{v},\mathbf{u}) = \overline{f(\mathbf{u},\mathbf{v})}$ for all $\mathbf{u},\mathbf{v} \in V$. **13.5**

Hoffman polynomial (of graph G): A polynomial $h(x)$ of minimum degree such that $h(A_G) = J$. **39.3**

Hölder norm (of a vector): See *p-norm.*

Hölder p-norm (of a hypermatrix): The vector p-norm of the hypermatrix. **15.8**

homogeneous (digraph): Either symmetric or asymmetric. **49.8**

homogeneous (element of graded algebra $A = \bigoplus_{k\in\mathbb{N}} A_k$): An element of some A_k. **14.9**

homogeneous (pencil associated with $A(x) = A_0 + xA_1 \in \mathbb{D}[x]^{m\times n}$): $A(x_0, x_1) = x_0A_0 + x_1A_1 \in \mathbb{D}[x_0, x_1]^{m\times n}$. **32.4**

homogeneous (polynomial): All terms have the same degree. **32.1**

homogeneous (system of linear equations): A system in which all the constants are zero. **1.4**

Householder matrix: See *Householder transformation.*

Householder reflector: See *Householder transformation.*

Householder transformation (defined by $\mathbf{v} \in \mathbb{C}^n$): The matrix $I - \frac{2}{\|\mathbf{v}\|_2^2}\mathbf{v}\mathbf{v}^*$. **51.5**

Householder vector: The vector $\mathbf{v}$ used to define a Householder transformation. **51.5**

hyperbolic SVD decomposition (of matrix pair $(G, \mathcal{J})$): A decomposition of G, $G = W\Sigma B^{-1}$, where W is orthogonal, Σ is diagonal, and B is $\mathcal{J}$–orthogonal. **59.5**

hypermatrix, d-hypermatix: d-dimensional matrix (usually with $d \geq 3$). **15.1**

I

IAP: See *inertially arbitrary pattern.*

ideal (of domain $\mathbb{D}$): A nonempty subset I of $\mathbb{D}$ such that if $a, b \in I$ and $p, q \in \mathbb{D}$, then $pa + qb \in I$. **32.1**

idempotent: A matrix or linear transformation that squares to itself. **2.7**, **3.6**

identity matrix: A diagonal matrix having all diagonal elements equal to one. **1.2**

identity pattern (of order n): The $n \times n$ diagonal pattern with + diagonal entries. **42.1**

identity transformation: A linear operator that maps each vector to itself. **3.1**

IEP: See *inverse eigenvalue problem.*

IF-RCF matrix: A block diagonal matrix of the form $C(a_1) \oplus \cdots \oplus C(a_s)$, where $a_i(x)$ divides $a_{i+1}(x)$ for $i = 1, \ldots, s-1$. **6.7**

ill-conditioned (input $\mathbf{z}$ for P): Some small relative perturbation of $\mathbf{z}$ causes a large relative perturbation of $P(\mathbf{z})$. **50.4**

image: See *range.*

imaginary part (of complex number $a + bi$): b. **Preliminaries**

immanant: A function f_λ from complex square matrices to complex numbers defined by the irreducible character of a partition λ of n, specifically, $f_\lambda(M) = \sum_{\pi\in S_n} \chi_\lambda(\pi) \prod_{i=1}^{n} m_{i\pi(i)}$. **43.10**

implicit restarting (of the Arnoldi algorithm): Apply a sequence of implicitly shifted QR steps to an m-step Arnoldi or Lanczos factorization to obtain a truncated form of the implicitly shifted QR-iteration. **57.5**

imprimitive (digraph): Not primitive. **40.6**

imprimitive (matrix A): The digraph $\Gamma(A)$ is imprimitive. **40.6**

improper (divisor of a in a domain): An associate of a or a unit. **32.1**

incidence matrix (of a graph): A matrix with rows indexed by the vertices and columns indexed by the edges, having i, j entry 1 if vertex v_i is an endpoint of edge e_j and 0 otherwise. **39.4**

incidence matrix (of subsets $S_1, S_2, \ldots, S_m$ of a finite set $\{x_1, x_2, \ldots, x_n\}$): The $m \times n$ (0,1)-matrix $M = [m_{ij}]$ in which $m_{ij} = 1$ if and only if $x_j \in S_i$. **43.3**

($\pm$1)-incidence matrix (of a 2-design): A matrix W whose rows are indexed by the elements x_i of X and whose columns are indexed by the blocks B_j having $w_{ij} = -1$ if $x_i \in B_j$ and $w_{ij} = +1$ otherwise. **44.2**

incomplete Cholesky decomposition: A preconditioner for a Hermitian positive definite matrix A of the form $M = LL^*$, where L is a sparse lower triangular matrix. **54.4**

incomplete *LU* decomposition: A preconditioner for a general matrix A of the form $M = LU$, where L and U are sparse lower and upper triangular matrices. **54.4**

inconsistent: A system of linear equations that has no solution. **1.4**

indefinite (Hermitian matrix A): Neither A nor $-A$ is positive semidefinite. **9.4**

independent (set of vertices): See *coclique.*

independent (subspaces W_i): $\mathbf{w}_1 + \cdots + \mathbf{w}_k = \mathbf{0}$ and $\mathbf{w}_i \in W_i, i = 1, \ldots, k$ implies $\mathbf{w}_i = \mathbf{0}$ for all $i = 1, \ldots, k$. **2.3**

index (of eigenvalue): The smallest integer k such that the k-eigenspace equals the $k+1$-eigenspace. **6.1**

index (of matrix A): The smallest integer k such that $\operatorname{rank}\left(A^k\right) = \operatorname{rank}\left(A^{k+1}\right)$ (= index of eigenvalue 0). **27.2**

index (of square nonnegative matrix P): The index of the spectral radius of P. **10.3**

index (of $A \in \mathrm{H}_0$): See Section **32.3**.

index of imprimitivity (of irreducible matrix A): The greatest common divisor of the lengths of all cycles in the digraph $\Gamma(A)$; same as period. **40.7**

index of primitivity: See *exponent.*

individual condition number (for eigenvalue λ): $\frac{\|\mathbf{x}\|_2 \|\mathbf{y}\|_2}{|\mathbf{y}^* \mathbf{x}|}$ where $(\mathbf{y}, \lambda, \mathbf{x})$ is an eigentriplet. **21.1**

induced basis: The nonzero images in the quotient V/W of vectors in a basis that contains a basis for W. **2.3**

induced norm: The matrix norm induced by the family of vector norms $\| \cdot \|$ is $\|A\| = \max_{\mathbf{x} \neq 0} \frac{\|A\mathbf{x}\|}{\|\mathbf{x}\|}$. **50.3**

induced subdigraph (of digraph $\Gamma = (V, E)$): A subdigraph $\Gamma' = (V', E')$ containing all arcs from E with both endpoints in V'. **40.1**

induced subgraph (of graph $G = (V, E)$): A subgraph $G' = (V', E')$ containing all edges from E with both endpoints in V'. **39.1**

inertia (of complex square matrix A): The ordered triple $\mathrm{in}(A) = (\pi(A), \nu(A), \delta(A))$ where $\pi(A)$ is the number of eigenvalues of A with positive real part, $\nu(A)$ is the number of eigenvalues of A with negative real part, and $\delta(A)$ is the number of eigenvalues of A on the imaginary axis. **9.3**, **26.1**

inertia preserving (real square matrix A): The inertia of AD is equal to the inertia of D for every nonsingular real diagonal matrix D. **26.3**

inertially arbitrary pattern (IAP): A sign pattern A of size n such that every possible ordered triple (p, q, z) of nonnegative integers $p, q,$ and z with $p + q + z = n$ can be achieved as the inertia of some $B \in Q(A)$. **42.6**

infinite dimensional (vector space): A vector space that is not finite dimensional. **2.2**

initial (minor): See Section **29.3**

injective: See *one-to-one.*

inner distribution: Vector parameter of an association scheme. **39.6**

inner inverse (of matrix $A \in F^{m \times n}$): A matrix $X \in F^{n \times m}$ satisfying $AXA = A$. **27.4, 31.5**

inner product (on vector space V over $F = \mathbb{R}$ or $\mathbb{C}$): A function $\langle\cdot,\cdot\rangle\colon V \times V \rightarrow F$ satisfying certain conditions. For $F = \mathbb{R}$, $\langle\cdot,\cdot\rangle$ is symmetric, bilinear, and positive definite. **5.1**

inner product space: A real or complex vector space with an inner product. **5.1**

integral domain: A commutative ring without zero divisors and containing identity 1. **32.1**

internal direct sum: See *direct sum.*

intersection (of two graphs $G = (V, E)$ and $G' = (V', E')$): The graph with vertex set $V \cap V'$, and edge (multi)set $E \cap E'$. **39.1**

intersection numbers: Parameters of an association scheme. **39.6**

P**-invariant face** (of K-nonnegative matrix P): $PF \subseteq F$. **36.1**

invariant factors (of IF-RCF matrix $C(a_1) \oplus \cdots \oplus C(a_s)$): The polynomials $a_i(x), i = 1, \ldots s$. **6.7**

invariant factors (of matrix or linear operator $A \in F^{n\times n}$): The invariant factors of an IF-RCF matrix similar to A. **6.7**

invariant factors (of a matrix over a domain): See Section **32.1**.

invariant factors rational canonical form (of matrix $A \in F^{n\times n}$): An IF-RCF matrix similar to A. **6.7**

invariant factors rational canonical form (of a linear operator): See Section **6.7**.

invariant factors rational canonical form matrix: See *IF-RCF matrix.*

invariant polynomials: See *invariant factors.*

invariant subspace (of linear operator $T : V \rightarrow V$): A subspace U of V such that for all $\mathbf{u} \in U$, $T(\mathbf{u}) \in U$. **3.6**

invariant subspace (of matrix $A \in \mathbb{C}^{n\times n}$): A subspace $\mathcal{X}$ of $\mathbb{C}^n$ $A\mathcal{X} \subseteq \mathcal{X}$. **20.1**

inverse (of square matrix A): A matrix B such that $AB = BA = I$. **1.5**

inverse (of linear transformation $T : V \rightarrow W$): A linear transformation $S : W \rightarrow V$ such that $TS = I_W$ and $ST = I_V$. **3.7**

[1]-inner inverse (of matrix $A \in \mathbb{C}^{m\times n}$): See *inner inverse.*

[2]-inner inverse (of matrix $A \in \mathbb{C}^{m\times n}$): See *outer inverse.*

inverse eigenvalue problem: The problem of constructing a matrix with prescribed structural and spectral constraints. **28.1**

inverse eigenvalue problem with prescribed entries: Construct a matrix with given eigenvalues subject to given entries in given positions. **28.1**

inverse iteration: The power method applied to the inverse of a shifted matrix. **55.1**

inverse M**-matrix**: An invertible matrix whose inverse is an M-matrix. **10.5**

inverse nonnegative: A square sign pattern that allows an entrywise nonnegative inverse. **42.8**

inverse-positive (real square matrix A): A is nonsingular and $A^{-1} \geq 0$. **10.5**

inverse positive (square sign pattern): Allows an entrywise positive inverse. **42.8**

invertible (matrix or linear transformation): Has an inverse. **1.5**, **3.7**

$\mathbb{D}$**-invertible** (matrix in $\mathbb{D}^{n\times n}$): Has an inverse within $\mathbb{D}^{n\times n}$. **32.2**

irreducible (element a of a domain): a is not a unit and every divisor of a is an associate of a or a unit. **32.2**

irreducible (matrix): Not reducible. **10.2**, **38.3**

K**-irreducible** (K-nonnegative matrix P): The only P-invariant faces of cone K are the trivial faces. **36.1**

irreducible components (of matrix A): The diagonal blocks in the Frobenius normal form of A. **38.3**

isolated vertex: A vertex of a graph having no incident edges. **39.1**

isomorphic (graphs $G = (V, E)$ and $G' = (V', E')$): There exist bijections $\phi : V \rightarrow V'$ and $\psi : E \rightarrow E'$, such that $v \in V$ is an endpoint of $e \in E$ if and only if $\phi(v)$ is an endpoint of $\psi(e)$. **39.1**

isomorphic (vector spaces): There is an isomorphism from one vector space onto the other. **3.7**

isomorphism (of vector spaces): An invertible linear transformation. **3.7**

isoperimetric number: A parameter of a simple graph. **39.5**, **47.5**

iterative method (for solving a linear system $A\mathbf{x} = \mathbf{b}$): Any algorithm that starts with an initial guess $\mathbf{x_0}$ for the solution and successively modifies that guess in an attempt to obtain improved approximate solutions $\mathbf{x_1}, \mathbf{x_2}, \ldots$. **54.1**

J

$\mathcal{J}$–orthogonal: Alphabetized under *orthogonal.*

Jacobi matrix: A real tridiagonal matrix having the product of corresponding sub- and super-diagonal entries positive. **22.7**

Jacobi method (for computing EVD of A): A sequence of matrices, $A_0 = A$, $A_{k+1} = G(i_k, j_k, c, s)\ A_k G(i_k, j_k, c, s)^T$, $k = 1, 2, \ldots$, where $G(i_k, j_k, c, s)$ is a Givens rotation matrix. **55.7**

Jacobi rotation: A Givens rotation used in the Jacobi method. **55.7**

join (of disjoint graphs $G = (V, E)$ and $G' = (V', E')$: The union of $G \cup G'$ and the complete bipartite graph with vertex set $V \cup V'$ and partition $\{V, V'\}$. **39.1**

join (of faces F, G of cone K): Face generated by $F \cup G$. **36.1**

Jordan basis (for matrix A): The ordered set of columns of C where $\mathrm{JCF}(A) = C^{-1}AC$. **6.2**

Jordan basis (of a linear operator): See Section **6.2**.

Jordan block (of size k with eigenvalue λ): The $k \times k$ matrix having every diagonal entry equal to λ, every first superdiagonal entry equal to 1, and every other entry equal to 0. **6.2**

Jordan canonical form (of matrix A): A Jordan matrix that is similar to A. **6.2**

Jordan canonical form (of a linear operator T): ${}_{\mathcal{B}}[T]_{\mathcal{B}}$ that is a Jordan matrix. **6.2**

Jordan chain (above eigenvector $\mathbf{x}$ for eigenvalue λ of A): A sequence of vectors $\mathbf{x}_0 = \mathbf{x}, \mathbf{x}_1, \ldots, \mathbf{x}_h$ satisfying $\mathbf{x}_i = (A - \lambda I)\mathbf{x}_{i+1}$ for $i = 0, \ldots, h-1$ (where h is the depth of $\mathbf{x}$). **6.2**

Jordan invariants (of matrix or linear operator A): The set of distinct eigenvalues of A and for each eigenvalue λ, the number b_λ and sizes $p_1, \ldots, p_{b_\lambda}$ of the Jordan blocks with eigenvalue λ in a Jordan canonical form of A. **6.2**

Jordan matrix: A block diagonal matrix having Jordan blocks as the diagonal blocks. **6.2**

K

k**-tree**: Alphabetized under *tree.*

K**-irreducible,** K**-nonnegative,** K**-positive,** K**-semipositive**: Alphabetized under *irreducible, nonnegative, positive, semipositive.*

ker: See *kernel.*

kernel (ker) (of a linear transformation): The set of vectors mapped to zero by the transformation. **3.5**

kernel (ker) (of matrix A): The set of solutions to $A\mathbf{x} = \mathbf{0}$. **2.4**

Kronecker product (of matrices A and B): The block matrix whose i, j block is $a_{ij}B$ **11.4**

Kruskal rank (of set of vectors S): The largest r so that every set of r vectors in S is linearly dependent. **15.6**

Krylov matrix (of matrix A, vector $\mathbf{x}$, and $k \in \mathbb{Z}^+$): $[\mathbf{x}, A\mathbf{x}, A^2\mathbf{x}, \cdots, A^{k-1}\mathbf{x}]$. **55.8**

Krylov space: A subspace of the form $\mathrm{Span}\{\mathbf{q}, A\mathbf{q}, A^2\mathbf{q}, \ldots, A^{k-1}\mathbf{q}\}$, where A is an $n \times n$ matrix and $\mathbf{q}$ is an n-vector. **54.1**, **57.1**

Ky Fan k norms (of $A \in \mathbb{C}^{m \times n}$): $\|A\|_{K,k} = \sum_{i=1}^{k} \sigma_i(A)$. **24.3**

L

L**-matrix** (sign pattern or real matrix A): For every $B \in Q(A)$, the rows of B are linearly independent. **42.3**

Lagrange interpolation polynomial: The jth Lagrange interpolation polynomial determined by the nodes $x_1, \ldots, x_n$ is defined by $L_j^{\mathbf{x}}(x_j) = 1$ and $L_j^{\mathbf{x}}(x_i) = 0$ for $i \neq j$. **22.4**

Lanczos algorithm (for Hermitian matrices): A short recurrence for constructing an orthonormal basis for a Krylov space. **54.2**

Laplacian: See *Laplacian matrix.*

Laplacian eigenvalues (of simple graph G): The eigenvalues of the Laplacian matrix of G. **39.4**

Laplacian matrix (of simple graph G): The matrix $D - \mathcal{A}_G$, where D is the diagonal matrix of vertex degrees and $\mathcal{A}_G$ is the adjacency matrix of G. **39.4**

Laplacian matrix (of weighted graph G): The matrix $D - \mathcal{A}_G$, where D is the diagonal degree matrix and $\mathcal{A}_G$ is the adjacency matrix of G. **47.1, 48.4**

largest size of a zero submatrix: The maximum of $r + s$ such that the matrix has an $r \times s$ (possibly vacuous) zero submatrix. **38.1**

LDU **factorization**: A factorization of a matrix as the product of a unit lower triangular matrix, a diagonal matrix, and a unit upper triangular matrix. **1.6**

leading coefficient: The first (highest power of the variable) nonzero coefficient in a polynomial or matrix polynomial. **18.1**

leading entry: The first nonzero entry in a row of a matrix in REF. **1.3**

leading principal minor: The determinant of a leading principal submatrix. **4.2**

leading principal submatrix: A principal submatrix lying in rows and columns 1 to k. **1.2**

least squares data fitting: See Section **52.2**.

least squares problem ($A\mathbf{x} = \mathbf{b}$): Find a vector $\mathbf{x} \in \mathbb{R}^n$ such that $\|\mathbf{b} - A\mathbf{x}\|_2$ is minimized. **5.8, 52.1**

least squares solution: A solution to a least squares problem. **5.8**, **52.1**

left divisible: Matrix polynomial $P(x)$ is left divisible by matrix polynomial $P_1(x)$ if the left remainder of $P(x)$ on division by $P_1(x)$ is zero. **18.1**

left eigenpair (of $A \in \mathbb{C}^{n\times n}$): A pair (L, Y) where Y is a basis matrix for left invariant subspace $\mathcal{Y}$ and $Y^*A = LY^*$. **20.1**

left eigenvector (of matrix A): A left eigenvector of $A \in F^{n\times n}$ is nonzero row vector $\mathbf{y}$ over F such that there exists a scalar λ such that $\mathbf{y}A = \lambda\mathbf{y}$. **4.4** (As used in perturbation theory and numerical linear algebra over the complex numbers, e.g., Chapters 20, 21, 56, 57, a left eigenvector of $A \in \mathbb{C}^{n\times n}$ is customarily a nonzero (column) vector $\mathbf{y} \in \mathbb{C}^n$ such that there exists a scalar $\lambda \in \mathbb{C}$ such that $\mathbf{y}^*A = \lambda\mathbf{y}^*$.)

left invariant subspace (of matrix $A \in \mathbb{C}^{n\times n}$): An invariant subspace of $\mathcal{Y}^*$. **20.1**

left quotient (of matrix polynomial $P(x)$ on division by matrix polynomial $P_1(x)$): The matrix polynomial $Q(x)$ where $P(x) = P_1(x)Q(x) + R(x)$, provided the leading coefficient of $P(x)$ is nonsingular and $\deg R(x) < \deg P_1(x)$ or $R(x)$ is zero. **18.1**

left remainder (of matrix polynomial $P(x)$ on division by matrix polynomial $P_1(x)$): The matrix polynomial $R(x)$ where $P(x) = P_1(x)Q(x) + R(x)$, provided the leading coefficient of $P(x)$ is nonsingular and $\deg R(x) < \deg P_1(x)$ or $R(x)$ is zero. **18.1**

left singular space: See *singular spaces.*

left singular vector: See *singular vectors.*

length (of a walk, path, cycle in a graph or digraph): The number of edges (arcs) in the walk. **39.1**, **40.1**

length (of a permutation cycle): The number of elements in the cycle. **Preliminaries**

length (of a vector): See *norm.*

$(C, 0)$-**limit** (of complex sequence $\{a_m\}_{m=0,1,\ldots}$): Ordinary limit $\lim_{m\to\infty} a_m$. **10.1**

$(C, 1)$-**limit** (of complex sequence $\{a_m\}_{m=0,1,\ldots}$): $\lim_{m\to\infty} m^{-1} \sum_{s=0}^{m-1} a_s$. **10.1**

(C, k)-**limit** (of complex sequence $\{a_m\}_{m=0,1,\ldots}$): Defined inductively from $(C, k-1)$-limit. **10.1**.

line (of a matrix): A row or column. **38.1**

line graph (of simple graph G): The simple graph that has as vertices the edges of G, and vertices are adjacent if the corresponding edges of G have an endpoint in common. **39.2**
linear combination: A (finite) sum of scalar multiples of vectors. **2.1**
linear equation: An equation of the form $a_1x_1 + \cdots + a_nx_n = b$. **1.4**
linear form: See *linear functional.*
linear functional: A linear transformation from a vector space to the field. **3.8**
m**-linear map**: See *multilinear map.*
linear mapping: See *linear transformation.*
linear matrix equation: A matrix equation of the form $\sum_{i=1}^{\ell} A_iXB_i - Q = 0$,where $\ell \geq 1$, $Q \in \mathbb{C}^{k\times p}$, $A_i \in \mathbb{C}^{k\times m}$, $B_i \in \mathbb{C}^{n\times p}$, for $i = 1, \ldots, \ell$, and $X \in \mathbb{C}^{m\times n}$ is the unknown. **19.2**
linear operator: A linear transformation from a vector space to itself. **3.1**
linear preserver (of function f**)**: A linear operator $\phi : \mathcal{V} \to \mathcal{V}$ such that $f(\phi(A)) = f(A)$ for every $A \in \mathcal{V}$, where $\mathcal{V}$ is a subspace of $F^{m\times n}$. **30.1**
linear preserver problem (corresponding to the property P): The problem of characterizing all linear (bijective) maps on a subspace of matrices satisfying P. **30.2**
linear transformation: A function from a vector space to a vector space that preserves addition and scalar multiplication. **3.1**
linear transformation associated to matrix A: The transformation that multiplies each vector in F^n by A. **3.3**
linearly dependent (set of vectors): There is a linear combination of the vectors with at least one nonzero coefficient, that is equal to the zero vector. **2.1**
linearly independent (set of vectors): Not linearly dependent. **2.1**
linked: Two disjoint Jordan curves in $\mathbb{R}^3$ such that there is no topological 2-sphere in $\mathbb{R}^3$ separating them. **39.2**
linklessly embeddable: There is an embedding of graph G in $\mathbb{R}^3$ such that no two disjoint cycles of G are linked. **39.2**
little-oh: Function f is $o(g)$ if the limit of $\frac{|f|}{|g|}$ is 0. **Preliminaries**
local similarity: A map $\phi : F^{n\times n} \to F^{n\times n}$ such that for every $A \in F^{n\times n}$ there exists an invertible $R_A \in F^{n\times n}$ such that $\phi(A) = R_AAR_A^{-1}$. **30.4**
Loewner matrix (defined by vectors **a, b, c, d**): $L(\mathbf{a}, \mathbf{b}, \mathbf{c}, \mathbf{d}) := \left[\frac{c_i - d_j}{a_i - b_j}\right]_{i,j=1}^{n}$. **22.5**
Loewner (partial) ordering (on Hermitian matrices A, B): $A \succ B$ if $A - B$ is positive definite and $A \succeq B$ if $A - B$ is positive semidefinite. **9.5**
logarithm (of a square complex matrix A): Any matrix B such that $e^B = A$. **17.3**
look-ahead strategy: A technique to overcome breakdown in some algorithms. **54.3**
loop: An edge (arc) of a graph (directed graph) having both endpoints equal. **40.1**
Lovász parameter: A parameter of a simple graph. **39.5**
lower Hessenberg (matrix A): A^T is upper Hessenberg. **11.2**
lower shift matrix: See *downshift matrix.*
lower triangular matrix: A matrix such that every entry having row number less than column number is zero. **1.2**, **11.2**
Löwner (partial) ordering: See *Loewner (partial) ordering*
LU **factorization**: A factorization of a matrix as the product of a unit lower triangular matrix and an upper triangular matrix. **1.6**, **51.3**
Lyapunov diagonally semistable (real square matrix A): There exists a positive diagonal matrix D such that $AD + DA^T$ is positive semidefinite. **26.5**
Lyapunov diagonally stable (real square matrix A): There exists a positive diagonal matrix D such that $AD + DA^T$ is positive definite. **26.5**
Lyapunov scaling factor (of real square matrix A): A positive diagonal matrix D such that $AD + DA^T$ is positive (semi)definite. **26.5**

M

M**-matrix** (real square matrix A): A can be written as $A = sI - P$ with P a nonnegative matrix and s a scalar satisfying $s > \rho(P)$. **10.5**

M_0**-matrix**: (real square matrix A): A can be written as $A = sI - P$ with P a nonnegative matrix and s a scalar satisfying $s \geq \rho(P)$. **10.5**

machine epsilon: The distance between the number one and the next larger floating point number. **50.6**

main angles (of a graph): The cosines of the angles between the eigenspaces of the adjacency matrix and the all-ones vector. **39.3**

main diagonal (of a matrix): The set of diagonal entries of a matrix. **1.2**

majorizes: Weakly majorizes and the sums of all entries are equal. **Preliminaries**

matching (of a graph): A set of mutually disjoint edges. **4.3**, **41.1**

matrices: Plural of *matrix.*

matrix: A rectangular array of elements of a field. **1.2** Or, if specifically stated, a rectangular array of elements of a domain, ring, or algebra. The following standard matrix terms are applied to the matrices over a domain $\mathbb{D}$ viewed as in the quotient field of $\mathbb{D}$: determinant, minor, rank. **32.2** The following standard matrix terms are applied to matrices over a Bezout domain within the domain: kernel, range, system of linear equations, coefficient matrix, augmented matrix. **32.3**

matrix condition number: See *condition number (of matrix A for linear systems).*

matrix cosine: See *cosine.*

matrix direct sum: A block diagonal matrix. **2.4**, **11.2**

matrix exponential: See *exponential.*

matrix equation: An equation of the form $F(X) = 0$, where $X \in \mathbb{C}^{m\times n}$ and $F : \mathbb{C}^{m\times n} \to \mathbb{C}^{k\times p}$. **19.1**

matrix field: A subring of the matrix ring $F^{n\times n}$ that is a field. **31.3**

matrix function: A function of a square complex matrix; can be defined using power series, Jordan canonical form, polynomial interpretation, Cauchy integral, etc. **17.1**

matrix logarithm: See *logarithm.*

matrix of a transformation T (with respect to bases $\mathcal{B}$ and $\mathcal{C}$): The matrix consisting of the coordinate vectors with respect to $\mathcal{C}$ of the images under T of the vectors in $\mathcal{B}$. **3.3**

matrix norm $\|\cdot\|$: A family of real-valued functions defined on $m \times n$ real or complex matrices for all positive integers m and n, such that for all matrices A and B (where A and B are compatible for the given operation) and all scalars, (1) $\|A\| \geq 0$, and $\|A\| = 0$ implies $A = 0$; (2) $\|\alpha A\| = |\alpha|\|A\|$; (3) $\|A+B\| \leq \|A\|+\|B\|$; (4) $\|AB\| \leq \|A\|\,\|B\|$. **50.3**

matrix pencil: See *pencil.*

matrix polynomial: A polynomial in a single variable with coefficients that are $m \times n$ matrices over F. **18.1**, **19.3** Many standard matrix terms are applied to matrix polynomials; see Chapter **18**.

matrix representing f **relative to basis** $\mathcal{B} = (\mathbf{w_1}, \mathbf{w_2}, \dots, \mathbf{w_n})$: The matrix whose i, j-entry is $f(\mathbf{w_i}, \mathbf{w_j})$. **13.1** Also applied to φ-sesquilinear form. **13.4**

matrix sine: See *sine.*

matrix sign function: See *sign (of a matrix).*

matrix square root: See *square root, principal square root.*

matrix–vector product: The result of multiplying a matrix and a vector. **1.2**

maximal (ideal I of domain $\mathbb{D}$): The only ideals that contain I are I and $\mathbb{D}$, and $I \neq \mathbb{D}$. **32.1**

maximal (sign-nonsingular-sign pattern matrix): If a zero entry is set nonzero, then the resulting pattern is not SNS. **42.2**

maximal rank (of sign-pattern A): $\max\{\operatorname{rank} B : \ B \in Q(A)\}$. **42.6**

maximum column sum norm (of matrix $A \in \mathbb{C}^{m\times n}$): $\|A\|_1 = \max_{1\leq j\leq n} \sum_{i=1}^{m} |a_{ij}|$. **50.3**
maximum multiplicity (of simple graph G): Maximum multiplicity of any eigenvalue among matrices in $\mathcal{S}(G)$. **46.1**
maximum nullity (of simple graph G): Maximum of $\operatorname{null} A$ among matrices in $\mathcal{S}(G)$. **46.1** Maximum nullity of other families of matrices of a simple graph are also in Chapter **46**.
maximum rank (of space of hypermatrices $F^{n_1\times\cdots\times n_d}$): Maximum of the ranks of the hypermatrices in $F^{n_1\times\cdots\times n_d}$. **15.5**
maximum row sum norm (of matrix $A \in \mathbb{C}^{m\times n}$): $\|A\|_\infty = \max_{1\leq i\leq m} \sum_{j=1}^{n} |a_{ij}|$. **50.3**
max-plus semiring: The set $\mathbb{R} \cup \{-\infty\}$, equipped with the addition $(a, b) \mapsto \max(a, b)$ and the multiplication $(a, b) \mapsto a + b$. The identity element for the addition, zero, is $-\infty$, and the identity element for the multiplication, unit, is 0. **35.1**
measure of relative separation (of positive real numbers a, b): $|\sqrt{a/b} - \sqrt{b/a}|$. **24.4**
meet (of faces F, G of cone K): $F \cap G$. **36.1**
metric: A distance function. **Preliminaries**
MIEP: See *multiplicative inverse eigenvalue problem.*
minimal (matrix norm $\|\cdot\|$): For any matrix norm $\|\cdot\|_\nu$, $\|A\|_\nu \leq \|A\|$ for all A implies $\|\cdot\|_\nu = \|\cdot\|$. **50.3**
minimal polynomial (of matrix A): The unique monic polynomial of least degree for which $q_A(A) = 0$. **4.4**
minimal rank (of sign pattern A): $\min\{\operatorname{rank} B : B \in Q(A)\}$. **42.6**
minimal residual (MINRES) algorithm (to solve $H\mathbf{x} = \mathbf{b}$ with H preconditioned Hermitian): At each step k, the approximation $\mathbf{x}_k$ is of the form
$\mathbf{x}_k \in \mathbf{x}_0 + \operatorname{Span}\{\mathbf{r}_0, H\mathbf{r}_0, \ldots, H^{k-1}\mathbf{r}_0\}$ for which the 2-norm of the residual, $\|\mathbf{r}_k\|_2$, is minimal. **54.2**
minimal sign-central (sign pattern): A sign-central pattern that is not sign-central if any column of A is deleted. **42.10**
minimally connected (digraph): Strongly connected and the deletion of any arc produces a subdigraph that is not strongly connected. **40.8**
minimally potentially stable (sign pattern A): A is a potentially stable, irreducible sign pattern such that replacing any nonzero entry by zero results in a pattern that is not potentially stable. **42.4**
minimum co-cover (of a $(0, 1)$-matrix): A co-cover with the smallest number of 1s. **38.1**
minimum cover (of a $(0, 1)$-matrix): A cover with the smallest number of lines. **38.1**
minimum degree (of simple graph G): The minimum of the degrees of the vertices of G. **46.1**
minimum-norm least squares solution: The least squares solution of minimum Euclidean norm. **52.1**
minimum rank (of simple graph G): The minimum of $\operatorname{rank} A$ among matrices $A \in \mathcal{S}(G)$. **46.1** Minimum rank of other families of matrices of a simple graph are also in Chapter **46**.
minor (of graph G): Any graph that can be obtained from G by a sequence of edge deletions, vertex deletions, and contractions. **39.2**, **46.5**
minor (of a matrix): The determinant of a submatrix; for the i, j-minor, the submatrix is obtained by deleting row i and column j. **4.1**
minor monotone (graph parameter ζ): For any minor H of G, $\zeta(H) \leq \zeta(G)$. **46.5**
MINRES: See *minimal residual.*
mixed graph: A graph in which loops and multiple edges are allowed and that may contain both directed and undirected edges. **34.4**
Möbius function: $\mu : \mathbb{N} \mapsto \{-1, 0, 1\}$ is defined by $\mu(1) = 1$, $\mu(m) = (-1)^e$ if m is a product of e distinct primes, and $\mu(m) = 0$ otherwise. **28.5**

$\mathbb{D}$-module: A generalization of vector space over a field; an additive group with a (scalar) multiplication by elements $a \in \mathbb{D}$ that satisfies the standard distribution properties and $1\mathbf{v} = \mathbf{v}$ for all $\mathbf{v} \in \mathbb{D}$. The following standard terms are also applied to modules over a Bezout domain: linear combination, basis (may not exist), standard basis for $\mathbb{D}^n$, dimension (if there is a basis). **32.3**

monic (polynomial $p(x)$): The coefficient of the highest power of x in $p(x)$ is 1. **32.1**

monotone (minor) (graph parameter): See *minor monotone.*

monotone (real vector $\mathbf{v} = [v_i]$): $v_1 \geq v_2 \geq \cdots \geq v_n$. **38.4**

monotone (vector norm $\|\cdot\|$): For all $\mathbf{x}, \mathbf{y}$, $|\mathbf{x}| \leq |\mathbf{y}|$ implies $\|\mathbf{x}\| \leq \|\mathbf{y}\|$. **50.1**

Moore–Penrose pseudo-inverse (of matrix $A \in \mathbb{C}^{m\times n}$): A matrix $A^\dagger \in \mathbb{C}^{n\times m}$ satisfying: $AA^\dagger A = A$; $A^\dagger AA^\dagger = A^\dagger$; $(AA^\dagger)^* = AA^\dagger$; $(A^\dagger A)^* = A^\dagger A$. **5.7**, **27.1**

Moore–Penrose inverse (of a sign pattern): Analog of the Moore–Penrose inverse of a real matrix. **42.8**

multibigraph (of nonnegative integer matrix A): Like the bigraph of A, except that edge $\{i, j'\}$ has multiplicity a_{ij}. **41.2**

multigrid preconditioner: A preconditioner designed for problems arising from partial differential equations discretized on grids. **54.4**

multilinear form: A multilinear map into the field F. **14.1**

multilinear functional: A multilinear map into the field F (same as multilinear form). **15.2**

multilinear matrix multiplication: Multiplication of a d-hypermatrix by d matrices. **15.1**

multilinear map (m-linear map): A map φ from $V_1 \times \cdots \times V_m$ into U that is linear on each coordinate. **14.1**

multilinear rank (of a hypermatrix): d-tuple of ranks of the d flattenings of a d-hypermatrix. **15.7**

multiplicative (map $\phi : F^{n\times n} \to F^{n\times n}$): $\phi(AB) = \phi(A)\phi(B)$, for all $A, B \in F^{n\times n}$. **30.4**

multiplicative D-stable (real square matrix A): DA is stable for every positive diagonal matrix D. **26.3**

multiplicative inverse eigenvalue problem (MIEP): Given $B \in \mathbb{C}^{n\times n}$ and $\lambda_1, \ldots, \lambda_n \in \mathbb{C}$ find a diagonal matrix $D \in \mathbb{C}^{n\times n}$ such that $\sigma(BD) = \{\lambda_1, \ldots, \lambda_n\}$. **28.9**

multiplicative perturbation (of $A \in \mathbb{C}^{m\times n}$): $D_L^* AD_R$ for some $D_L \in \mathbb{C}^{m\times m}, D_R \in \mathbb{C}^{n\times n}$. **21.3**

multiplicative preserver: A multiplicative map preserving a certain property. **30.4**

multiplicity (of an eigenvalue): See *algebraic multiplicity, geometric multiplicity.*

multiplicity (of a singular value): The dimension of the right or left singular space. **58.1**

multiset: An unordered list of elements that allows repetition. **Preliminaries**

N

`NaN`: Result of an operation that is not a number in a standard-conforming floating point system. **50.6**

nearly decomposable ($(0, 1)$-matrix): Fully indecomposable and each matrix obtained by replacing a 1 with a 0 is partly decomposable. **38.2**

nearly reducible (matrix A): Irreducible and each matrix obtained from A by replacing a nonzero entry with a zero is reducible. **38.3**

nearly sign-central: A sign pattern that is not sign-central, but can be augmented to a sign-central pattern by adjoining a column. **42.10**

nearly sign nonsingular (NSNS) (sign pattern): A square pattern having at least two nonzero terms in the expansion of its determinant, with precisely one nonzero term having opposite sign to the others. **42.2**

negative definite (real symmetric or Hermitian bilinear form f): $-f$ is positive definite. **13.2**, **13.5**

negative definite (matrix A): $-A$ is positive definite. **49.5**
negative semidefinite (real symmetric or Hermitian bilinear form f): $-f$ is positive semidefinite. **13.2**, **13.5**
negative set of edges α (in a signed bipartite graph): $\mathrm{sgn}(\alpha)$ is -1. **41.1**
negative stable (complex polynomial): Its roots lie in the open left half-plane. **26.2**
negative stable (complex square matrix): Its eigenvalues lie in the open left half-plane. **26.2**
neighbor (of vertex v): Any vertex adjacent to v. **39.1**
NIEP: See *nonnegative inverse eigenvalue problem.*
nilpotent: A matrix or linear transformation that can be multiplied by itself a finite number of times to obtain the zero matrix or transformation. **2.7**, **3.6**
node: See *vertex.*
noncommutative algorithms: Algorithms that do not use commutativity of multiplication. **61.2**
nondefective (matrix $A \in F^{n\times n}$): For each eigenvalue of A (over algebraic closure of F), the geometric multiplicity equals the algebraic multiplicity. **4.4**
nondegenerate (bilinear form f on vector space V): The rank of f is equal to $\dim V$. **13.1** Also applied to φ-sesquilinear form. **13.4**
nonderogatory (matrix $A \in F^{n\times n}$): The geometric multiplicity of each eigenvalue of A (over algebraic closure of F) is 1; equivalently the minimal and characteristic polynomials of A are equal. **4.4**
nondifferentiable (boundary point μ of convex set S): There is more than one support line of S passing through μ. **25.2**
non-Hermitian Lanczos algorithm See Section **54.3**.
nonlinear eigenvalue problem: To find solutions λ such that the linear system $T(\lambda)\mathbf{x} = 0$ has a nontrivial solution $\mathbf{x}$, where $T(\cdot) : D \to \mathbb{C}^{n\times n}$ is a family of matrices depending on a complex parameter $\lambda \in D \subseteq \mathbb{C}$. **60.1**
nonnegative (real matrix): All the entries are nonnegative. **10.1**
nonnegative (sign pattern): All the entries are nonnegative. **42.8**
K**-nonnegative** (matrix $A \in \mathbb{R}^{n\times n}$): $AK \subseteq K$. **36.1**
K**-nonnegative** (vector $\mathbf{v} \in \mathbb{R}^n$): $\mathbf{v} \in K$. **36.1**
nonnegative inverse eigenvalue problem: Construct a nonnegative matrix with given eigenvalues. **28.3**
nonnegative integer rank (of nonnegative integer matrix A): The minimum k such that there exists an $m \times k$ nonnegative integer matrix B and a $k \times n$ nonnegative integer matrix C with $A = BC$. **41.3**
nonnegative stable (complex square matrix A): The real part of each eigenvalue of A is nonnegative. **10.5**
nonprimary matrix function: Function of a matrix defined via the Jordan canonical form using different branches for f and its derivatives for two Jordan blocks for the same eigenvalue. **17.1**
nonseparable (graph or digraph): Connected and does not have a cut-vertex. **49.1**
nonsingular (linear transformation): A linear transformation whose kernel is zero. **3.7**
nonsingular (square matrix): An invertible matrix. **1.5**
nonsymmetric algebraic Riccati equation (NARE): A matrix equation of the form $C + XA + DX - XBX = 0$ where $A \in \mathbb{C}^{n\times n}$, $B \in \mathbb{C}^{n\times m}$, $C \in \mathbb{C}^{m\times n}$, $D \in \mathbb{C}^{m\times m}$, and $X \in \mathbb{C}^{m\times n}$ is the unknown. **19.4**
norm (of a vector $\mathbf{v}$, in an inner product space): $\sqrt{\langle \mathbf{v}, \mathbf{v}\rangle}$. **5.1**
norm: See *vector norm, matrix norm*, or *[specific] norm.*
1-norm (of vector $\mathbf{x} \in \mathbb{C}^n$): $\|\mathbf{x}\|_1 = |x_1| + |x_2| + \cdots + |x_n|$. **50.1**
1-norm (of matrix $A \in \mathbb{C}^{m\times n}$): See *maximum column sum norm.*
2-norm (of vector $\mathbf{x} \in \mathbb{C}^n$): $\|\mathbf{x}\|_2 = \sqrt{|x_1|^2 + |x_2|^2 + \cdots + |x_n|^2}$. **50.1**

2-norm (of matrix $A \in \mathbb{C}^{m\times n}$): See *maximum column sum norm.*

∞-norm (of vector $\mathbf{x} \in \mathbb{C}^n$): $\|\mathbf{x}\|_\infty = \max\limits_{1\le i\le n} |x_i|$. **50.1**

∞-norm (of matrix $A \in \mathbb{C}^{m\times n}$): See *maximum row sum norm.*

***M*-norm** (where $\|\cdot\|$ is a vector norm and M is a nonsingular matrix): $\|\mathbf{x}\|_M = \|M\mathbf{x}\|$. **50.1**

$\mathcal{M}$-norm (matrix norm): Norm induced by a family of M_n-norms for $\mathcal{M} = \{M_n : n \ge 1\}$ a family of nonsingular $n \times n$ matrices. **50.3**

***p*-norm** (of matrix $A \in \mathbb{C}^{m\times n}$, with $p \ge 1$): The matrix norm induced by the (vector) p-norm. **50.1**

***p*-norm** (of vector $\mathbf{x} \in \mathbb{C}^n$, with $p \ge 1$): $\|\mathbf{x}\|_p = (|x_1|^p + \cdots + |x_n|^p)^{\frac{1}{p}}$. **50.1**

p, q, r-norm (of hypermatrix A): The induced (p, q, r) hypermatrix norm. **15.8**

normal (complex square matrix or linear operator): Commutes with its Hermitian adjoint. **8.2**

normal equations (for the least squares problem $A\mathbf{x} = \mathbf{b}$): The system $A^*A\mathbf{x} = A^*\mathbf{b}$. **5.8**

normalized (representation $\pm(m/b^{p-1})b^e$ of a floating point number): $b^{p-1} \le m < b^p$. **50.6**

normalized generalized inverse (of matrix $A \in F^{m\times n}$ where F has an involutory field automorphism): A matrix $X \in F^{n\times m}$ satisfying $AXA = A, XAX = X$, and $(AX)^* = AX$. **31.5**

normalized immanant: Function defined by the irreducible character of a partition λ of n, specifically, $f_\lambda(M) = \frac{1}{\chi_\lambda(\varepsilon)} \sum_{\pi\in S_n} \chi_\lambda(\pi) \prod_{i=1}^n m_{i\pi(i)}$. **43.10**

normalized Laplacian matrix (of weighted graph G):

$$(\mathcal{L}_G)_{i,j} = \begin{cases} 1 - \frac{w(v_i,v_i)}{d_i} & \text{if } i = j \text{ and } d_i \ne 0 \\ -\frac{w(v_i,v_j)}{\sqrt{d_i d_j}} & \text{if } i \ne j \text{ and } w(v_i, v_j) > 0 \\ 0 & \text{otherwise} \end{cases}. \quad \mathbf{47.1}$$

normalized scaling (of rectangular matrix A): A scaling DAE of A with $\det(D) = \det(E) = 1$. **10.6**

normwise backward error (of an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$): $\eta(\tilde{\lambda}, \tilde{\mathbf{x}}) = \min\{||E|| : (A + E)\tilde{\mathbf{x}} = \tilde{\lambda}\tilde{\mathbf{x}}\}$. **63.2**

NSNS: See *nearly sign nonsingular.*

nuclear norm (of a matrix or hypermatrix): See *Schatten*-1 *norm.*

null graph: A graph with no vertices. **39.1**

null space: See *kernel.*

nullity: The dimension of the kernel. **2.4**, **3.5**

numerical radius (of $A \in \mathbb{C}^{n\times n}$): $w(A) = \max\{|\mu| : \mu \in W(A)\}$. **25.1**

numerical range(of $n\times n$ complex matrix A): $W(A) = \{\mathbf{u}^*A\mathbf{u} : \mathbf{u}^*\mathbf{u} = 1, \mathbf{u} \in \mathbb{C}^n\}$. **8.1**, **25.1**

numerical rank (of matrix A, with respect to the threshold τ): $\min\{\text{rank}(A+E) : \|E\|_2 \le \tau\}$. **52.9**

numerically orthogonal (vectors $\mathbf{x}, \mathbf{y}$): $|\mathbf{x}^T\mathbf{y}| \le \varepsilon\|\mathbf{x}\|_2\|\mathbf{y}\|_2$. **59.1**

numerically orthogonal matrix: Each pair of its columns are numerically orthogonal. **59.1**

numerically stable (algorithm): Produces results that are roughly as accurate as the errors in the input data allow. **50.8**

numerically unstable (algorithm): Allows rounding and truncation errors to produce results that are substantially less accurate than the errors in the input data allow. **50.8**

O

oblique (subspaces $\mathcal{X}$ and $\mathcal{Y}$ of $\mathbb{C}^n$ with $\dim \mathcal{X} = \dim \mathcal{Y}$): For any basis matrices X and Y for $\mathcal{X}$ and $\mathcal{Y}$, Y^*X is nonsingular. **20.1**

odd (permutation): Can be written as the product of an odd number of transpositions. **Preliminaries**

odd (cycle in a sign pattern): The length of the simple or composite cycle is odd. **42.1**
off-diagonal entry: An entry in a matrix that is not a diagonal entry. **1.2**
off-norm (of $A \in \mathbb{C}^{n\times n}$): The Frobenius norm of the matrix consisting of all off-diagonal elements of A and a zero diagonal. **55.7**
oh: See *big-oh, little-oh.*
one-to-one (linear transformation T): $\mathbf{v}_1 \neq \mathbf{v}_2$ implies $T(\mathbf{v}_1) \neq T(\mathbf{v}_2)$. **3.5**
onto (linear transformation): The codomain equals the range. **3.5**
open left half-plane: $\{z \in \mathbb{C} : \mathrm{re}(z) < 0\}$. **Preliminaries**
open right half-plane: $\{z \in \mathbb{C} : \mathrm{re}(z) > 0\}$. **Preliminaries**
open sector (from ray $e^{i\alpha}$ to ray $e^{i\beta}$): The set of rays $\{re^{i\theta} \ : \ r > 0, \alpha < \theta < \beta\}$. **42.12**
operator norm: See *induced norm.*
order (of a graph): The number of vertices in the graph. **39.1**
order (of a square matrix): See *size.*
order (of a hypermatrix): A d-hypermatrix has order d. **15.1**
order (of a tensor): A d-tensor has order d. **15.2**
oriented (vertex-edge) incidence matrix (of graph G): A matrix obtained from the incidence matrix of G by replacing a 1 in each column by a -1. **39.4**
orthogonal (vectors): Two vectors whose inner product is 0. **5.2**
orthogonal (set of vectors): Any two distinct vectors in the set are orthogonal. **5.2**
$\mathcal{J}$–**orthogonal** (real matrix B) $B^T\mathcal{J}B = \mathcal{J}$ (where $\mathcal{J}$ is a nonsingular real symmetric matrix). **59.5**
orthogonal basis: A basis that is orthogonal as a set. **5.2**
orthogonal complement (of subset S): Subspace of vectors orthogonal to every vector in S. **5.2**
orthogonal iteration: Method for computing the EVD of real symmetric A: given starting $n\times p$ matrix X_0 with orthonormal columns, the sequence of matrices $Y_{k+1} = AX_k$, $Y_{k+1} = X_{k+1}R_{k+1}$ $k = 0, 1, 2, \ldots$, where $X_{k+1}R_{k+1}$ is the reduced QR factorization of Y_{k+1}. **55.1**
orthogonal matrix: A real or complex matrix Q such that $Q^TQ = I$. **5.2**, **7.5**, **8.1**
orthogonal projection: Projection onto a subspace along its orthogonal complement. **5.4**
orthogonal with respect to symmetric bilinear form f (vectors $\mathbf{v}, \mathbf{u}$): $f(\mathbf{u}, \mathbf{v}) = 0$. **13.2**
orthonormal (set of vectors): An orthogonal set of unit vectors. **5.2**
orthonormal basis: A basis that is orthonormal as a set. **5.2**
oscillatory (real square matrix A): A is totally nonnegative and A^k is totally positive for some integer $k \geq 1$. **29.1**
outer inverse (of matrix $A \in \mathbb{C}^{m\times n}$): A matrix $X \in C^{n\times m}$ satisfying $XAX = X$. **27.4**
outer product (of hypermatrices): See Section **15.1**.
overflow: $|x|$ equals or exceeds a threshold at or near the largest floating point number. **50.6**
outerplanar (graph G): There is an embedding of G into $\mathbb{R}^2$ with the vertices on the unit circle and the edges contained in the unit disc. **39.2**

P

P**-invariant face**: Alphabetized under *invariant.*
P**-matrix**: A square complex matrix in which every principal minor is positive. **26.2**
P_0**-matrix**: A square real matrix in which every principal minor is nonnegative. **49.9**
P_0^+**-matrix**: A square complex matrix in which every principal minor is nonnegative and at least one principal minor of each order is positive. **26.2**
$P_{0,1}$**-matrix**: A square real matrix in which every principal minor is nonnegative and every diagonal element is positive. **49.9**
pairwise orthogonal (orthogonal projections P and Q): $PQ = QP = 0$. **8.2**

Parter vertex: See *Parter–Wiener vertex.*

partial completely positive matrix: A square partial matrix B such that every fully specified principal submatrix of B is a completely positive matrix, whenever b_{ij} is specified, then so is b_{ji} and $b_{ji} = b_{ij} \geq 0$. **49.4**

partial copositive matrix: A square real partial matrix B such that every fully specified principal submatrix of B is a copositive matrix and whenever b_{ij} is specified, then so is b_{ji} and $b_{ji} = b_{ij}$. **49.6**

partial doubly nonnegative matrix: A square partial matrix B such that every fully specified principal submatrix of B is a doubly nonnegative matrix and whenever b_{ij} is specified, then so is b_{ji} and $b_{ji} = b_{ij} \geq 0$. **49.4**

partial entry sign symmetric P-matrix (P_0-matrix, $P_{0,1}$-matrix): A square real partial matrix B such that every fully specified principal submatrix of B is an entry sign symmetric P-matrix (P_0-matrix, $P_{0,1}$-matrix) and if both b_{ij} and b_{ji} are specified, then $b_{ij}b_{ji} > 0$ or $b_{ij} = b_{ji} = 0$. **49.11**

partial entry weakly sign symmetric P-matrix (P_0-matrix, $P_{0,1}$-matrix): A square real partial matrix B such that every fully specified principal submatrix of B is an entry weakly sign symmetric P-matrix (P_0-matrix, $P_{0,1}$-matrix) and if both b_{ij} and b_{ji} are specified, then $b_{ij}b_{ji} \geq 0$. **49.11**

partial Euclidean distance matrix: A square real partial matrix B such that every diagonal entry is specified and equal to 0, every fully specified principal submatrix of B is a Euclidean distance matrix, and whenever b_{ij} is specified, then so is b_{ji} and $b_{ji} = b_{ij}$. **49.3**

partial inverse M-matrix: A square partial matrix such that every fully specified principal submatrix is an inverse M-matrix and every specified entry is nonnegative. **49.8**

partial M-matrix (M_0-matrix): A square partial matrix such that every fully specified principal submatrix is an M-matrix (M_0-matrix) and every specified off-diagonal entry is nonpositive. **49.7**

partial matrix: A rectangular array in which some entries are specified and others are not. **49.1**

partial nonnegative P-matrix (P_0-matrix, $P_{0,1}$-matrix): A square partial matrix such that every fully specified principal submatrix is a nonnegative P-matrix (P_0-matrix, $P_{0,1}$-matrix) and all specified entries are nonnegative. **49.10**

partial P-matrix (P_0-matrix, $P_{0,1}$-matrix): A square real partial matrix such that every fully specified principal submatrix is a P-matrix (P_0-matrix, $P_{0,1}$-matrix). **49.9**

partial positive definite (positive semidefinite) matrix: A square complex partial matrix B such that every fully specified principal submatrix of B is positive definite (positive semidefinite) and whenever b_{ij} is specified, then so is b_{ji} and $b_{ji} = \overline{b_{ij}}$. **49.2**

partial positive P-matrix: A square partial matrix such that every fully specified principal submatrix is a positive P-matrix and all specified entries are positive. **49.10**

partial Q-matrix: A square real partial matrix such that $S_k(A) > 0$ for every $k = 1, 2, \ldots, n$ for which all principal minors are fully specified. **49.12**

partial semidefinite ordering: See *Loewner ordering.*

partial strictly copositive matrix: A square real partial matrix B such that every fully specified principal submatrix of B is a strictly copositive matrix and whenever b_{ij} is specified, then so is b_{ji} and $b_{ji} = b_{ij}$. **49.6**

partial totally positive (totally nonnnegative, totally nonpositive) matrix: A real partial matrix such that every fully specified principal submatrix is totally positive (totally nonnnegative, totally nonpositive). **49.13**

partial k-tree: A subgraph of a k-tree. **46.1**

partitioned (matrix): A matrix partitioned into submatrices by partitions of the row and column indices. **11.1**

partly decomposable ($n \times n$ $(0,1)$-matrix): Has a $p \times q$ zero submatrix for positive integers p, q with $p + q = n$. **38.2**

path (in a graph): A walk with all vertices distinct. **39.1**

path (in a digraph): A walk with all vertices distinct. **40.1**

path (in sign pattern A): A formal product of the form $\gamma = a_{i_1 i_2} a_{i_2 i_3} \ldots a_{i_k i_{k+1}}$, where each of the elements is nonzero and the index set $\{i_1, i_2, \ldots, i_{k+1}\}$ consists of distinct indices. **42.1**

path-clique (digraph): The induced subdigraph of every alternate path to a single arc is a clique. **49.8**

path-connected (subset S of complex numbers): There exists a path in S (i.e., a continuous function from [0,1] to S) from any point in S to any other point in S. **Preliminaries**

path cover number (of simple graph G): The minimum number of vertex disjoint induced paths of G that cover all vertices of G. **46.1**

pattern (of matrix A): The $(0,1)$-matrix obtained from A by replacing each nonzero entry with a 1. **38.1**

pattern block triangular form (partial matrix B): The adjacency matrix of $\mathcal{D}(B)$ is in block triangular form. **49.1**

PEIEP: See *inverse eigenvalue problem with prescribed entries.*

pencil (defined by $A, B \in \mathbb{C}^{n \times n}$): $A - xB$, or pair (A, B). **56.1**

pencil (in $\mathbb{D}[x]^{m \times n}$): A matrix $A(x) = A_0 + xA_1$, $A_0, A_1 \in \mathbb{D}^{m \times n}$. **32.4**

perfect elimination ordering: An elimination ordering that does not produce any fill elements during Gaussian elimination. **41.2, 53.5**

perfect matching: A matching M in which each vertex of G is in one edge of M. **4.3**, **41.1**

perfectly well determined to high relative accuracy (singular values of A): Changing an arbitrary nonzero entry $a_{k\ell}$ to $\theta a_{k\ell}$, with arbitrary $\theta \neq 0$ causes a relative perturbation in σ_i bounded by $|\theta|$ and $1/|\theta|$. **59.3**

period (of access equivalence class J of reducible square nonnegative matrix P): The period of the irreducible matrix $P[J]$. **10.3**

period (of irreducible square nonnegative matrix P): Greatest common divisor of the lengths of the cycles of the digraph of P. **10.2**

period (of reducible square nonnegative matrix P): The least common multiple of the periods of its basic classes. **10.3**

permanent (of $n \times n$ matrix A): $\operatorname{per}(A) = \sum_{\pi \in S_n} \prod_{i=1}^{n} a_{i\pi(i)}$ (also defined for rectangular matrices). **43.1**

permutation: A 1-1 onto function from a set to itself. **Preliminaries**

permutation equivalent (matrices A, B): There exist permutation matrices P and Q such that $B = PAQ$. **43.1**

permutation invariant norm ($\|\cdot\|$): $\|P\mathbf{x}\| = \|\mathbf{x}\|$ for all vectors $\mathbf{x}$ and all permutation matrices P. **50.1**

permutation invariant absolute norm ($\|\cdot\|$): $\|\mathbf{x}\| = \||\mathbf{x}|\|$ and $\|\mathbf{x}\| = \|P\mathbf{x}\|$ for all $\mathbf{x} \in \mathbb{R}^n$ and all permutation matrices $P \in \mathbb{R}^{n \times n}$. **24.3**

permutation matrix: A matrix whose rows are a rearrangement of the rows of the identity matrix. **1.2**

permutation pattern: A square sign pattern matrix with entries 0 and $+$, where the entry $+$ occurs precisely once in each row and in each column. **42.1**

permutation similar (square matrices A, B): There exists a permutation matrix P such that $B = P^{-1}AP$ $(= P^T AP)$. **38.2**

permutational equivalence (of sign pattern A): A product of the form $P_1 A P_2$, where P_1 and P_2 are permutation patterns. **42.1**

permutational similarity (of sign pattern A): A product of the form $P^T AP$, where P is a permutation pattern. **42.1**

Perron branch (at vertex v of a tree): The Perron value of the corresponding bottleneck matrix is maximal among all branches at v. **48.3**

Perron value (of square nonnegative matrix P): The spectral radius of P. **10.1**

perturbation (of matrix A): $A + \Delta A$. **21.1**

perturbation (of scalar β): $\beta + \Delta\beta$. **21.1**

perturbation (of vector $\mathbf{v}$): $\mathbf{v} + \Delta\mathbf{v}$. **21.1**

Petrie matrix: A $(0, 1)$-matrix with the 1s in each of its columns occurring in consecutive rows. **41.2**

pfaffian (of square matrix A of even size): a polynomial in the entries of A such that if A is skew-symmetric, then $\det A = (\text{pf } A)^2$. **4.3**

PIEP: Affine parameterized inverse eigenvalue problem. **28.8**

pinching (of a matrix): Defined recursively. See Section **24.4**.

pivot: An entry of a matrix in a pivot position. **1.3**

pivot column: A column of a matrix that contains a pivot position. **1.3**

pivot position: A position in a matrix in row echelon form that contains a leading entry. **1.3**

pivot row: A row of a matrix that contains a pivot position. **1.3**

planar (graph G): There is an embedding of G into $\mathbb{R}^2$ (i.e., G can be drawn in the plane without crossing edges). **39.2**

$PLDU$ **factorization**: A factorization of a row permutation of a given matrix as the product of a unit lower triangular matrix, diagonal matrix, and a unit upper triangular matrix. **1.6**

PLU **factorization**: A factorization of a row permutation of a given matrix as the product of a unit lower triangular matrix and an upper triangular matrix. **1.6**, **51.3**

PO: See *potentially orthogonal.*

pointed (cone K): $K \cap -K = \{0\}$. **9.5, 36.1**

polar decomposition (of matrix $A \in \mathbb{C}^{m\times n}$ with $m \geq n$): A factorization $A = UP$ where $P \in \mathbb{C}^{n\times n}$ is positive semidefinite and $U \in \mathbb{C}^{m\times n}$ satisfies $U^*U = I_n$. **24.1**

polar form: See *polar decomposition.*

polynomial matrix equation (PME): A matrix equation of the form $\sum_{i=0}^{\ell} A_i X^i = 0$, where $\ell \geq 2$, $A_i \in \mathbb{C}^{m\times m}$, $i = 0, 1, \ldots, \ell$, and $X \in \mathbb{C}^{m\times m}$ is the unknown. **19.3**

polynomial restarting (of the Arnoldi algorithm): Use $\psi(A)\mathbf{v}$ instead of vector $\mathbf{v}$ when restarting. **57.4**

polytope: See *convex polytope.*

positionally symmetric: See *combinatorially symmetric.*

positive (linear map $\phi : \mathbb{C}^{n\times n} \to \mathbb{C}^{m\times m}$): $\phi(A)$ is positive semidefinite whenever A is positive semidefinite. **25.7**

positive (real matrix): All the entries are positive. **10.1**

K**-positive** (matrix $A \in \mathbb{R}^{n\times n}$): $AK \subseteq \text{int } K$. **36.1**

K**-positive** (vector $\mathbf{v} \in \mathbb{R}^n$): $\mathbf{v} \in \text{int } K$. **36.1**

positive definite (matrix): An $n \times n$ Hermitian matrix satisfying $\mathbf{x}^*A\mathbf{x} > 0$ for all nonzero $\mathbf{x} \in \mathbb{C}^n$. **5.1**, **9.4**

positive definite (real symmetric or Hermitian bilinear form f): $f(\mathbf{v}, \mathbf{v}) > 0$ for all nonzero $\mathbf{v} \in V$. **13.2**, **13.5**

positive P**-matrix**: A P-matrix in which every entry is positive. **49.10**

positive semidefinite (function $f : \mathbb{R} \to \mathbb{C}$): For each $n \in \mathbb{N}$ and all $x_1, x_2, \ldots, x_n \in \mathbb{R}$, the $n \times n$ matrix $[f(x_i - x_j)]$ is positive semidefinite. **9.5**

positive semidefinite (matrix): An $n \times n$ Hermitian matrix A satisfying $\mathbf{x}^*A\mathbf{x} \geq 0$ for all $\mathbf{x} \in \mathbb{C}^n$. **9.4**

positive semidefinite (real symmetric or Hermitian bilinear form f): $f(\mathbf{v}, \mathbf{v}) \geq 0$ for all $\mathbf{v} \in V$. **13.2**, **13.5**

positive semistable (complex square matrix): See *nonnegative stable.*

positive set α **of edges** (in a signed bipartite graph): $\text{sgn}(\alpha)$ is $+1$. **41.1**

positive stable (complex polynomial): Its roots lie in the open right half-plane. **26.2**
positive stable (complex square matrix): Its eigenvalues lie in the open right half-plane. **10.5**, **26.2**
k-potent (square sign pattern or ray pattern A): k is the smallest positive integer such that $A = A^{k+1}$. **42.13**
potentially orthogonal (PO) (square sign pattern): Allows an orthogonal matrix. **42.9**
potentially stable (square sign pattern A): Allows a stable matrix. **42.4**
Powell–Reid's complete (row and column) pivoting: A particular pivoting strategy for QR-factorization. **59.2**
power method: Method for computing the EVD of A: given starting vector $\mathbf{x}_0$, compute the sequences $\nu_k = \mathbf{x}_k^T A\mathbf{x}_k$, $\mathbf{x}_{k+1} = A\mathbf{x}_k/\|A\mathbf{x}_k\|$, $k = 0, 1, 2, \ldots$, until convergence. **55.1**
powerful (square sign or ray pattern A): All the powers $A^1, A^2, A^3, \ldots$, are unambiguously defined. **42.13**
precision: The number of digits, i.e., p in $x = \pm\left(\frac{m}{b^{p-1}}\right) b^e$. **50.6**
preconditioner: A matrix M designed to improve the performance of an iterative method for solving the linear system $A\mathbf{x} = \mathbf{b}$. **54.1**
preserves: Linear operator T preserves bilinear form f if $f(T\mathbf{u}, T\mathbf{v}) = f(\mathbf{u}, \mathbf{v})$ for all $\mathbf{u}, \mathbf{v}$. **13.1** Also applied to φ-sesquilinear form. **13.4**
preserves: Linear operator ϕ preserves subset of matrices $\mathcal{M}$ if $\phi(\mathcal{M}) \subseteq \mathcal{M}$. **30.1**
preserves: Linear operator ϕ preserves relation $\sim$ on matrix subspace $\mathcal{V}$ if $\phi(A) \sim \phi(B)$ whenever $A \sim B$, $A, B \in \mathcal{V}$. **30.1**
primary decomposition (of a nonconstant monic polynomial $q(x)$ over F): A factorization $q(x) = (h_1(x))^{m_1} \cdots (h_r(x))^{m_r}$, where the $h_i(x), i = 1, \ldots, r$ are distinct monic irreducible polynomials over F. **6.5**
primary factors: The factors in a primary decomposition. **6.5**
primary matrix function: Function of a matrix defined using the Jordan canonical form and using the same branch for f and its derivatives for each Jordan block for the same eigenvalue. **17.1**
prime (in domain $\mathbb{D}$): A nonzero, nonunit element p such that for any $a, b \in \mathbb{D}, p|ab$ implies $p|a$ or $p|b$. **32.1**
prime (ideal I of a domain): $ab \in I$ implies that either a or b is in I. **32.1**
primitive (digraph): There is a positive integer k such that for every pair of vertices u and v, there is a walk of length k from u to v. **40.6**
primitive (polynomial $f(x) \in F[x]$ with F a finite field): f is monic, $\deg f = m$, and f has a root in the finite extension $GF(q^m)$ of F that generates the multiplicative group of $GF(q^m)$. **31.3**
primitive (polynomial in $\mathbb{Z}[x]$): 1 is a g.c.d. of the coefficients. **32.1**
primitive matrix: A square nonnegative matrix whose digraph is primitive. **40.6**
primitive polynomial: A polynomial $f(x) \in F[x]$ of degree m over F is primitive if it is monic and has a root in the finite extension $GF(q^m)$ of F that generates the multiplicative group of $GF(q^m)$. **31.3**
principal angles (between subspaces X_1 and X_2 of $\mathbb{C}^n$): For $\dim X_1 = \dim X_2 = m \leq \frac{n}{2}$: Define $U_i \in \mathbb{C}^{n\times m}$ having columns of an orthonormal basis for $X_i, i = 1, 2$. Then the singular values of $U_2^* U_1$ are the cosines of the principal angles (same as *canonical angles*). Principal angles are also defined for more general X_1, X_2. **24.7**
principal ideal: An ideal generated by one element (in a domain). **32.1**
principal ideal domain domain (PID) $\mathbb{D}$: Any ideal of $\mathbb{D}$ is principal. **32.1**
principal minor: The determinant of a principal submatrix. **4.2**
principal logarithm (of a square complex matrix that has no real eigenvalues ≤ 0): The logarithm with all eigenvalues in the strip $\{\, z : -\pi < \mathrm{im}(z) \ < \pi \,\}$. **17.3**

principal square root (of a square complex matrix that has no real eigenvalues ≤ 0): The square root with each eigenvalue having real part > 0. **17.5**

principal submatrix: A submatrix lying in the same rows as columns. **1.2**, **11.1**

principal submatrix at a distinguished eigenvalue λ (of square nonnegative matrix P): The principal submatrix of P corresponding to a set of vertices of $\Gamma(P)$ having no access to a vertex of an access equivalence class C that satisfies $\rho(P[C]) > \lambda$. **10.3**

principal vectors (between subspaces X and Y of $\mathbb{C}^r$): See Section **24.7**.

product (of simple graphs): See (*strong*) *product.*

product, Cartesian (of simple graphs): See *Cartesian product.*

profile (of sparse matrix A): The number of elements in the envelope of A. **53.5**

projection (of a vector onto V_1 along V_2, assuming $V = V_1 \oplus V_2$): The (unique) part of the vector in V_1; also, the linear transformation that maps a vector to its projection. **3.6**

proper cone K (in finite-dimensional real vector space V): A convex cone that is closed, pointed, and full. **36.2**

proper subdigraph (of digraph $\Gamma = (V, E)$): A subdigraph $\Gamma' = (V', E')$ such that V' is a proper subset of V or E' is a proper subset of E. **40.1**

properly signed nest: See *allows a properly signed nest.*

Property C: An $n \times n$ M-matrix A satisfies property C if there exists a representation of A of the form $A = sI - P$ with $s > 0$, $P \geq 0$ and $\frac{P}{s}$ semiconvergent. **10.4**

Property L: A property that complex square matrices A, B have if their eigenvalues $\alpha_k, \beta_k, (k = 1, \cdots, n)$ may be ordered in such a way that the eigenvalues of $xA + yB$ are given by $x\alpha_k + y\beta_k$ for all complex numbers x and y. **8.2**, **33.3**

PSD square root (of a positive semidefinite matrix): The square root with each eigenvalue ≥ 0 (same as principal square root for a positive definite matrix). **9.3**

pseudo-code: An informal computer program used for writing algorithms. **50.7**

ε-**pseudoeigenvalue** (of matrix $A \in \mathbb{C}^{n\times n}$): A number $z \in \mathbb{C}$ such that there exists a nonzero vector $\mathbf{v} \in \mathbb{C}^n$ such that $\|A\mathbf{v} - z\mathbf{v}\| < \varepsilon\|\mathbf{v}\|$. **23.1**

ε-**pseudoeigenvector** (of matrix $A \in \mathbb{C}^{n\times n}$): A nonzero vector $\mathbf{v} \in \mathbb{C}^n$ such that there exists $z \in \mathbb{C}$ such that $\|A\mathbf{v} - z\mathbf{v}\| < \varepsilon\|\mathbf{v}\|$. **23.1**

ε-**pseudospectral abscissa** (of a complex square matrix): The rightmost extent of the ε-pseudospectrum. **23.3**

ε-**pseudospectral radius** (of a complex square matrix): The maximum magnitude of the ε-pseudospectrum. **23.3**

ε-**pseudospectrum** (of complex square matrix A): The set $\{z \in \mathbb{C} : z \in \sigma(A+E)$ for some $E \in \mathbb{C}^{n\times n}$ with $\|E\| < \varepsilon\}$. **23.1**

ε-**pseudospectrum of a matrix pencil**: See Section **23.5**.

ε-**pseudospectrum of a matrix polynomial**: See Section **23.5**.

ε-**pseudospectrum of a rectangular matrix**: See Section **23.5**.

Q

Q-**matrix**: For every $k = 1, 2, \ldots, n$ the sum $S_k(A)$ of all $k \times k$ principal minors of A is positive. **49.12**

QMR algorithm: Iterative method for solving a linear system using non-Hermitian Lanczos algorithm. **54.3**

QR factorization (of $A \in \mathbb{C}^{m\times n}$): $A = QR$ where Q is unitary and R is upper triangular. **5.5**

QR factorization with column pivoting (of $A \in \mathbb{R}^{m\times n}$): The factorization $A\Pi = Q\begin{bmatrix} R \\ 0 \end{bmatrix}$, where Π is a permutation matrix, Q is orthogonal, and R is $n \times n$ upper triangular. **59.2**

QR iteration: Method for computing the EVD of A: starting from the matrix $A_0 = A$, the sequence of matrices $A_k = Q_k R_k$, $A_{k+1} = R_k Q_k$, $k = 0, 1, 2, \ldots$ where $Q_k R_k$ is the QR factorization of A_k. **55.1**

quadrangular (bipartite graph): Simple and each pair of vertices with a common neighbor lie on a cycle of length 4. **41.1**

quadratic form (corresponding to symmetric bilinear form f): The map $g : V \to F$ defined by $g(\mathbf{v}) = f(\mathbf{v}, \mathbf{v})$, $\mathbf{v} \in V$. **13.2**

quadratic matrix equation (QME): A matrix equation of the form $A_0 + A_1 X + A_2 X^2 = 0$, $A_0, A_1, A_2, \in \mathbb{C}^{m\times m}$, $A_2 \neq 0$, and $X \in \mathbb{C}^{m\times m}$. **19.3**

quadratic matrix polynomial: A matrix polynomial of the form $A_0 + A_1 z + A_2 z^2$, $A_0, A_1, A_2, \in \mathbb{C}^{m\times m}$, $A_2 \neq 0$, and z is the unknown. **19.3**

qualitative class (of complex sign pattern $A = A_1 + iA_2$): $Q(A) = \{B_1 + iB_2 \ : \ B_1 \in Q(A_1) \text{ and } B_2 \in Q(A_2)\}$. **42.12**

qualitative class (of real matrix B): The qualitative class of $\text{sgn}(B)$. **42.1**

qualitative class (of sign pattern A): The set of all real matrices B with $\text{sgn}(B) = A$. **42.1**

quasi-triangular (matrix): A block triangular matrix with 1×1 and/or 2×2 blocks along the main diagonal. **7.2**, **56.2**

quiver: A quiver is a directed multigraph or digraph. **34.1**, **40.1**

quotient (of vector space V by subspace W): The set of additive cosets of W with operations $(v_1 + W) + (v_2 + W) = (v_1 + v_2) + W$ and $c(v + W) = (cv) + W$ for $c \in F$. **2.3**

quotient field (of an integral domain): The set of equivalence classes of all quotients $\frac{a}{b}, b \neq 0$, constructed the same way $\mathbb{Q}$ is constructed from $\mathbb{Z}$. **32.1**

R

(R, S)**-standard map**, (R, c, f)**-standard map**: Alphabetized under *standard.*

radix: The exponentiation base b in floating point number $x = \pm \left(\frac{m}{b^{p-1}}\right) b^e$. **50.6**

range (of linear transformation $T : V \to W$): $\{T(\mathbf{v}) : \mathbf{v} \in V\}$. **3.4**

range (of a matrix): The span of the columns. **2.4**

rank (of bilinear form f): The rank of a matrix representing f relative to an ordered basis. **13.1**. Also applied to φ-sesquilinear form. **13.4**

rank (of hypermatrix A): The rank of A is k if A is the sum of k Segre outer products of vectors (rank-one hypermatrices), but it cannot be written as sum of l Segre outer products for any l less than k. **15.3**

rank (of a matrix or linear transformation): The dimension of the range; for a matrix, equals the number of leading entries in the reduced row echelon form of the matrix. **1.3**, **2.4**, **3.5**

rank (of a matrix field): The rank of the identity element of the matrix field. **31.3**

rank (of a tensor $\mathbf{z}$): The rank of $\mathbf{z}$ is k if $\mathbf{z}$ is the sum of k decomposable tensors, but it cannot be written as sum of l decomposable tensors for any l less than k. **14.3**, **15.3**

rank retaining decomposition (of a tensor or hypermatrix): Expression in terms of the minimum number of decomposable (rank-one) tensors or hypermatrices. **59.2**

rank revealing (QR factorization (with pivoting) of A): Small singular values of A are revealed by correspondingly small diagonal entries of R. **59.2**

rank revealing decomposition (of real matrix A): A two-sided orthogonal decomposition of the form $A = U\widehat{R}V^T = U \begin{bmatrix} R \\ 0 \end{bmatrix} V^T$, where U and V are orthogonal, and R is upper triangular and reveals the (numerical) rank of A in the size of its diagonal elements. **52.9**

rank-spread (at vertex v of simple graph G): $r_v(G) = \text{mr}(G) - \text{mr}(G - v)$. **46.1**

rational canonical form: See *invariant factors rational canonical form* or *elementary divisors rational canonical form.*

rational function: A quotient of polynomials. **32.1**

ray nonsingular (ray pattern A): The Hadamard product $X \circ A$ is nonsingular for every entry-wise positive $n \times n$ matrix X. **42.12**

ray pattern: A matrix each of whose entries is either 0 or a ray in the complex plane represented by $e^{i\theta}$. **42.12**

ray pattern class (of ray pattern A): $Q(A) = \{B : b_{pq} = 0 \Leftrightarrow a_{pq} = 0$, and otherwise $\arg b_{pq} = \arg a_{pq}\}$. **42.12**

Rayleigh quotient: $\dfrac{\mathbf{x}^* A\mathbf{x}}{\mathbf{x}^*\mathbf{x}}$, where A is Hermitian and $\mathbf{x}$ is a nonzero vector. **9.2**

Rayleigh quotient (of invariant subspace $\mathcal{X}$ of A): The matrix L is the Rayleigh quotient of the basis matrix X of $\mathcal{X}$ if $AX = XL$. **20.1**

real generalized eigenspace: See Section **6.3**.

real generalized eigenvector: See Section **6.3**.

real-Jordan block (of size $2k$ with eigenvalue $\alpha + \beta i$): The $2k \times 2k$ matrix having k copies of $M_2(\alpha, \beta) = \begin{bmatrix} \alpha & \beta \\ -\beta & \alpha \end{bmatrix}$ on the (block matrix) diagonal, $k - 1$ copies of $I_2 = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$ on the first (block matrix) superdiagonal, and copies of $0_2 = \begin{bmatrix} 0 & 0 \\ 0 & 0 \end{bmatrix}$ everywhere else. **6.3**

real-Jordan canonical form (of real square matrix A): A real-Jordan matrix that is similar to A. **6.3**

real-Jordan matrix: A block diagonal real matrix having diagonal blocks that are Jordan blocks or real-Jordan blocks. **6.3**

real part (of complex number $a + bi$): a. **Preliminaries**

real structured ε-pseudospectrum (of real square matrix A): See Section **23.5**.

real vector space: A vector space over the field of real numbers. **1.1**

reduced digraph (of digraph Γ): A digraph whose vertices are the access equivalence classes of Γ (or $\{1, \ldots, k\}$ where k is the number of access equivalence classes) and having an arc from the ith vertex to the jth precisely when the ith access class has access to the jth access class. **10.1**, **40.5**

reduced QR factorization (of matrix $A \in \mathbb{C}^{m\times n}, m \geq n$): $A = \hat{Q}\hat{R}$ where columns of $\hat{Q}$ are orthonormal and R is upper triangular. **5.5**

reduced row echelon form (RREF): A matrix is in RREF if it is in REF, the leading entry in any nonzero row is 1, and all other entries in a column containing a leading entry are 0; matrix B is the RREF of matrix A if B is in RREF and A and B are row equivalent. **1.3**

reduced singular value decomposition (reduced SVD) (of complex matrix A): $A = \hat{U}\hat{\Sigma}\hat{V}^*$, $\hat{\Sigma} = \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_r) \in \mathbb{R}^{r\times r}$, where $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_r > 0$ and the columns of $\hat{U} \in \mathbb{C}^{m\times r}$ and the columns of $\hat{V} \in \mathbb{C}^{n\times r}$ are both orthonormal. **5.6**, **58.1**

reducible (square matrix A): There is a permutation matrix P such that $PAP^T = \begin{bmatrix} B & C \\ \mathbf{0} & D \end{bmatrix}$, where B, D are square. **10.1**, **38.3**

reducing eigenvalue (λ of $A \in \mathbb{C}^{n\times n}$): A is unitarily similar to $[\lambda] \oplus A_2$. **25.2**

REF: See *row echelon form.*

reflexive generalized inverse (of matrix $A \in F^{m\times n}$): A matrix $X \in F^{m\times n}$ satisfying $AXA = A$ and $XAX = X$. **27.4**, **31.5**

(k-)**regular** (graph): Every vertex has the same degree k. **39.2**

regular ($m \times n$ $(0,1)$-design matrix W): W is balanced and $W^TW = t(I + J)$ for some integer t. **44.4**

regular (matrix polynomial $P(x)$): $\det P(x)$ is not the zero polynomial. **18.1**

regular (pencil $A - xB$): There exists a $\lambda \in \mathbb{C}$ such that $A - \lambda B$ is nonsingular. **56.1**

regular (pencil $A_0 + xA_1 \in \mathbb{D}[x]^{n\times n}$): $\det(A_0 + xA_1)$ is not the zero polynomial, or equivalently, there exists a $\lambda \in \mathbb{D}$ such that $A_0 + \lambda A_1$ is nonsingular. **32.4**

relative backward error of the linear system: See Section **51.1**.

relative condition number: See *condition number.*

relative error (in approximation $\hat{\mathbf{z}}$ to $\mathbf{z}$): $\|\mathbf{z}-\hat{\mathbf{z}}\|/\|\mathbf{z}\|$. **50.4**

representation (of a quiver = (multi)digraph): An assignment of a finite dimensional vector space A_i over F to each vertex i, and to each arc (arrow) $\alpha : i \longrightarrow j$ a linear mapping $A_\alpha : A_i \to A_j$. **34.1**

requires: If P is a property referring to a real matrix, then a sign pattern A requires P if every real matrix in $Q(A)$ has property P. **42.1**

requires unique inertia (sign pattern A): $\text{in}(B_1) = \text{in}(B_2)$ for all symmetric matrices $B_1, B_2 \in Q(A)$. **42.6**

residual vector (of $\tilde{\mathbf{x}}$ when solving the linear system $A\mathbf{x} = \mathbf{b}$): The vector $\mathbf{r} = \mathbf{b} - A\tilde{\mathbf{x}}$. **51.3**

residual vector (at step k of an iterative method for solving $A\mathbf{x} = \mathbf{b}$): The vector $\mathbf{r}_k = \mathbf{b} - A\mathbf{x}_k$, where $\mathbf{x}_k$ is the approximate solution generated at step k. **54.1**

resolvent (of matrix $A \in \mathbb{C}^{n\times n}$): At a point $z \notin \sigma(A)$, the matrix $(zI - A)^{-1}$. **23.1**. The matrix valued function $R_A(z) = (A - zI)^{-1}$, where z is a complex variable. **20.2**

resolvent set (of matrix $A \in \mathbb{C}^{n\times n}$): The values of z for which the resolvent function is defined $(= \mathbb{C} \setminus \sigma(A))$. **20.2**

restarted GMRES algorithm, GMRES(j): Restart GMRES every j steps, using the latest iterate as the initial guess for the next GMRES cycle. **54.3**

right divisible: Matrix polynomial $P(x)$ is right divisible by matrix polynomial $P_1(x)$ if the right remainder of $P(x)$ on division by $P_1(x)$ is zero. **18.1**

right quotient (of matrix polynomial $P(x)$ on division by matrix polynomial $P_1(x)$): The matrix polynomial $Q(x)$ where $P(x) = Q(x)P_1(x) + R(x)$, provided the leading coefficient of $P(x)$ is nonsingular and $\deg R(x) < \deg P_1(x)$ or $R(x)$ is zero. **18.1**

right remainder (of matrix polynomial $P(x)$ on division by matrix polynomial $P_1(x)$): The matrix polynomial $R(x)$ where $P(x) = Q(x)P_1(x) + R(x)$, provided the leading coefficient of $P(x)$ is nonsingular and $\deg R(x) < \deg P_1(x)$ or $R(x)$ is zero. **18.1**

right singular vector: See *singular vectors.*

right singular space: See *singular spaces.*

ring automorphism of $F^{n\times n}$ induced by f: The map $\phi : F^{n\times n} \to F^{n\times n}$ defined by $\phi([a_{ij}]) = [f(a_{ij})]$. **30.4**

Ritz pair: $(\theta, \mathbf{v})$ where θ is the Ritz value for Ritz vector $\mathbf{v}$. **56.3**

Ritz value: The scalar θ for a Ritz vector. **56.3**

Ritz vector (of matrix of A from subspace $\mathcal{S}$ of $\mathbb{C}^n$): There is a $\theta \in \mathbb{C}$ such that $A\mathbf{v} - \theta\mathbf{v} \perp \mathcal{S}$. **56.3**

root invariant subspace (of eigenvalue λ of $A \in \mathbb{C}^{n\times n}$): The space spanned by the columns of the Jordan basis of A corresponding to the Jordan blocks containing λ. **20.1**

rook polynomials: Generating functions for rook numbers defined from permanents. **43.8**

rounding error: In one floating point arithmetic operation, the difference between the exact arithmetic operation and the floating point arithmetic operation; in more extensive calculations, refers to the cumulative effect of the rounding errors in the individual floating point operations. **50.6**

rounding mode: Maps $x \in \mathbb{R}$ to a floating point number $\text{fl}(x)$; default rounding mode in standard-conforming arithmetic is round-to-nearest, ties-to-even. **50.6**

Routh-Hurwitz matrix: See Section **26.2**.

row (of a matrix): The entries of a matrix lying in a horizontal line in the matrix. **1.2**

row echelon form (REF): A matrix is in REF if every zero row is below all nonzero rows and for two nonzero rows, the leading entry in the upper row is to the left of the leading entry of the lower row; matrix B is a REF of matrix A if B is in REF and A and B are row equivalent. **1.3**

row equivalent: Matrix A is row equivalent to matrix B if B can be obtained from A by a sequence of elementary row operations (equivalently, $B = QA$ for some invertible matrix Q). **1.3**

row equivalent (matrices $A, B \in \mathbb{D}^{m\times n}$): $B = QA$ for some $\mathbb{D}$-invertible matrix Q. **32.2**
row operation: See *elementary row operation.*
row signing (of (real or sign pattern) matrix A): DA where D is a signing. **42.3**
row space: The span of the rows of a matrix. **2.4**
row-stochastic (matrix): A square nonnegative matrix having all row sums equal to 1. **10.4**
row sum vector (of a matrix): The vector of row sums. **38.4**
RRD (of real matrix A): A decomposition $A = XDY^T$ with D a diagonal matrix and X and Y full column rank, well-conditioned matrices. **59.3**
RREF: See *reduced row echelon form.*

S

S**-matrix**: An $n \times (n+1)$ matrix B such that it is an S^*-matrix and the kernel of every matrix in $Q(B)$ contains a vector all of whose coordinates are positive. **42.3**
S^***-matrix**: An $n \times (n+1)$ matrix B such that each of the $n+1$ matrices obtained by deleting a column of B is an SNS matrix. **42.3**
SAP: See *spectrally arbitrary pattern.*
scalar: An element of a field. **1.1**
scalar matrix (transformation): A scalar multiple of the identity matrix (transformation). **1.2**, **3.2**
scaling (of a real matrix A): A matrix of the form D_1AD_2 where D_1 and D_2 are diagonal matrices with positive diagonal entries. **10.6**, **38.6**
Schatten-p norm (of $A \in \mathbb{C}^{m\times n}$): $\|A\|_{S,p} = \left(\sum_{i=1}^q \sigma_i^p(A)\right)^{1/p}$. **24.3**
Schatten-1 norm (of hypermatrix A): See **15.8**.
Schur complement: A matrix defined from a partitioned matrix. **4.2**, **11.3**, **12.2**
Schur product: See *Hadamard product.*
score vector: The row sum vector of a tournament matrix. **38.5**
SDR: See *system of distinct representatives.*
Segre outer product (of vectors $\mathbf{x}, \mathbf{y}, \mathbf{z}$): The hypermatrix having $x_iy_jz_k$ as its i, j, k entry. **15.1**
Seidel matrix (of simple graph G): The matrix $J - I - 2\mathcal{A}_G$. **39.4**
Seidel switching: An operation on simple graphs. **39.4**
self-adjoint: See *Hermitian.*
self-inverse sign pattern: An S^2NS-pattern A such that $B^{-1} \in Q(A)$ for every matrix $B \in Q(A)$. **42.2**
semiconvergent (square nonnegative matrix P): $\lim_{m\to\infty} P^m$ exists. **10.3**
semipositive (real matrix A): A is nonnegative and some element is positive. **10.1**
K**-semipositive** (matrix $A \in \mathbb{R}^{n\times n}$): A is K-nonnegative and $A \neq 0$. **36.1**
K**-semipositive** (vector $\mathbf{v} \in \mathbb{R}^n$): $\mathbf{v} \in K$ and $\mathbf{v} \neq 0$. **36.1**
semisimple: An eigenvalue having algebraic multiplicity equal to its geometric multiplicity. **4.4**
semistable matrix: Either positive semistable (i.e., nonnegative stable) or negative semistable, depending on section.
separation (between two square matrices A_1 and A_2): $\inf_{\|X\|_2=1} \|XA_1 - A_2X\|_2$. **21.1**
φ**-sesquilinear form** (on vector space V over field F with automorphism φ): A map f from $V\times V$ into F that satisfies $f(a\mathbf{u_1}+b\mathbf{u_2}, \mathbf{v}) = af(\mathbf{u_1}, \mathbf{v})+bf(\mathbf{u_2}, \mathbf{v})$ and $f(\mathbf{u}, a\mathbf{v_1}+b\mathbf{v_2}) = \varphi(a)f(\mathbf{u}, \mathbf{v_1}) + \varphi(b)f(\mathbf{u}, \mathbf{v_2})$. **13.4**
sesquilinear form (on a complex vector space): A φ-sesquilinear form where φ is complex conjugation. **13.4**
set of symmetric matrices associated with simple graph G: $\mathcal{S}(G) = \{B \in \mathcal{S}_n : G(B) = G\}$. **46.1**

sgn: See *sign.*

Shannon capacity: A parameter of a simple graph. **39.5**

shift: The scalar μ in a shifted matrix $A - \mu I$. **55.1**

shifted matrix (of matrix A): The matrix $A - \mu I$, where μ is the shift. **55.1**

shifted QR iteration: QR iteration of the shifted matrix. **55.1**

sign (denoted sign, of a complex number): A nonzero complex number; sign(0) = 1, otherwise the complex number with the same argument having absolute value 1. **Preliminaries**

sign (denoted sign, of a complex square matrix): A function defined from the Jordan canonical form of the matrix. **17.7**.

sign (denoted sgn, of a permutation): 1, if the permutation is even and −1, if the permutation is odd. **Preliminaries**

sign (denoted sgn, of a real number): $+, 0, -$ according as the number is $> 0, = 0, < 0$. **Preliminaries**

sign (denoted sgn, of a set α of edges in a signed bipartite graph): The product of the weights of the edges in α. **41.1**

sign (of a simple cycle in a sign pattern A): The product of the entries in the cycle. **42.1**

sign-central: A sign pattern matrix that requires centrality. **42.10**

sign nonsingular (SNS) (square sign pattern A): Every matrix $B \in Q(A)$ is nonsingular. **42.2**

sign pattern: A matrix whose entries are in $\{+, 0, -\}$. **42.1**

sign pattern class: See *qualitative class.*

sign pattern matrix: See *sign pattern.*

sign pattern of real matrix B: The sign pattern whose entries are the signs of the corresponding entries in B. **42.1**

sign potentially orthogonal SPO (square sign pattern): Does not have a zero row or zero column and every pair of rows and every pair of columns allows orthogonality. **42.9**

sign semistable (square sign pattern A): Every matrix $B \in Q(A)$ is semistable. **42.4**

sign singular (square sign pattern A): Every matrix $B \in Q(A)$ is singular. **42.2**

sign-solvable (system of linear equations $Ax = b$): For each $\tilde{A} \in Q(A)$ and each $\tilde{b} \in Q(b)$, the system $\tilde{A}x = \tilde{b}$ is consistent and the set $\{\tilde{x} :$ there exist $\tilde{A} \in Q(A)$ and $\tilde{b} \in Q(b)$ with $\tilde{A}\tilde{x} = \tilde{b}\}$ is entirely contained in one qualitative class. **42.3**

sign stable (square sign pattern A): Every matrix $B \in Q(A)$ is stable. **42.4**

sign symmetric (square matrix A): $\det A[\alpha, \beta] \det A[\beta, \alpha] \geq 0,\ \forall \alpha, \beta \subseteq \{1, \ldots, n\},\ |\alpha| = |\beta|$. **26.2**

signature (of a real symmetric or Hermitian bilinear form): The signature of a matrix representing the form relative to some basis. **13.2**, **13.5**

signature (of real symmetric or Hermitian matrix A): The number of positive eigenvalues minus the number of negative eigenvalues. **13.2**, **13.5**

signature (of composite cycle γ in sign pattern A): $(-)^{\sum_{i=1}^{m}(\ell_i - 1)}$ where the ℓ_i are the lengths of the simple cycles in γ. **42.1**

signature matrix: A ±1 diagonal matrix. **44.2**

signature pattern: A diagonal sign pattern matrix, each of whose diagonal entries is + or −. **42.1**

signature similarity (of square sign pattern A): A product of the form SAS, where S is a signature pattern. **42.1**

signed bigraph (of real matrix A): The weighted graph obtained from the bigraph of A weighting the edge $\{i, j'\}$ by $+1$ if $a_{ij} > 0$, and by -1 if $a_{ij} < 0$. **41.2**

signed bipartite graph: A weighted bipartite graph with weights $X = \{-1, 1\}$. **41.1**

signed 4-cockade: A 4-cockade whose edges are weighted by ±1 in such a way that every 4-cycle is negative. **41.2**

signed digraph (of $n \times n$ sign pattern A): The digraph with vertex set $\{1, 2, \ldots, n\}$ where (i, j) is an arc (bearing a_{ij} as its sign) if and only if $a_{ij} \neq 0$. **42.1**

significand: The (base b) integer m in floating point number $x = \pm \left(\frac{m}{b^{p-1}}\right) b^e$. **50.6**

signing (of order k): A nonzero $(0, 1, -1)$- or $(0, +, -)$-diagonal matrix of order k. **42.3**

signless Laplacian matrix (of graph G): The matrix $D + \mathcal{A}_G$, where D is the diagonal matrix of vertex degrees and $\mathcal{A}_G$ is the adjacency matrix of G. **39.4**

signless Laplacian matrix (of weighted graph G): The matrix $D + \mathcal{A}_G$, where D is the diagonal degree matrix and $\mathcal{A}_G$ is the adjacency matrix of G. **47.1**

similar (to matrix A): Any matrix of the form $C^{-1}AC$. **2.4**

similar (matrix fields): Two matrix subfields M and M' of $F^{n \times n}$ are similar if there exists a nonsingular matrix $P \in F^{n \times n}$ such that the similarity operator $A \mapsto P^{-1}AP$ defines a ring isomorphism between M and M', i.e., $M' = \{P^{-1}AP : A \in M\}$. **31.3**

similarity scaling (of square matrix A): A scaling DAD^{-1} of A. **10.6**

simple cycle (in a digraph): The induced subdigraph of the vertices in the cycle is the cycle and possibly some loops. **49.9**

simple cycle (in sign pattern A): See *k-cycle (in sign pattern A).*

simple digraph: A digraph with no loops (a digraph does not have multiple arcs). **40.1**

simple eigenvalue: An eigenvalue having algebraic multiplicity 1. **4.4**

simple graph: A graph with no loops where each edge has multiplicity at most one. **39.1**

simple invariant subspace: A direct sum of root invariant subspaces. **20.1**

simple row operation: A generalization of an elementary row operation used in domains. **32.2**

simple walk (in a digraph): A walk in which all vertices, except possibly the first and last, are distinct. **40.1**

sine (of complex square matrix A): The matrix defined by the sine power series, $\sin(A) = A - \frac{A^3}{3!} + \cdots + \frac{(-1)^k}{(2k+1)!} A^{2k+1} + \cdots$. **17.4**

single precision: Typically, floating point numbers that have machine epsilon roughly 10^{-7} and precision roughly 7 decimal digits. **50.6**

singular (matrix or linear operator): Not nonsingular. **1.5, 3.7**

singular (matrix polynomial $P(x)$): $\det P(x)$ is the zero polynomial. **18.1**

singular (pencil): A pencil that is not regular. **32.4**, **56.1**

singular space (right or left) (of complex matrix A): The subspace spanned by the right (or by the left) singular vectors of A. **58.1**

singular-triplet (of $A \in \mathbb{C}^{m \times n}$): A (left singular vector, singular value, right singular vector) triplet. **21.2**

singular value decomposition (SVD) (of matrix $A \in \mathbb{C}^{m \times n}$): $A = U\Sigma V^*$, $\Sigma = \operatorname{diag}(\sigma_1, \sigma_2, \ldots, \sigma_p) \in \mathbb{R}^{m \times n}$, $p = \min\{m, n\}$, where $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_p \geq 0$ and both $U = [\mathbf{u}_1, \mathbf{u}_2, \ldots, \mathbf{u}_m] \in \mathbb{C}^{m \times m}$ and $V = [\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n] \in \mathbb{C}^{n \times n}$ are unitary. Also forms with other dimensions. **5.6**, **24.1**, **58.1**

singular value vector (of complex matrix A): The vector of singular values of A in nonincreasing order. **24.1**

singular values (of a complex matrix): The diagonal entries σ_i of Σ in a singular value decomposition. **5.6**, **24.1**, **58.1**

singular vectors (of a complex matrix): Left: the columns of U, and right: the columns of V, both in a singular value decomposition. **5.6**, **58.1**

size (of matrix A): $m \times n$, where A is an $m \times n$ matrix; also m if $n = m$. **1.2**

Skeel condition number of the linear system $A\hat{\mathbf{x}} = \mathbf{b}$: $\operatorname{cond}(A, \hat{\mathbf{x}}) = \frac{\|\,|A^{-1}|\,|A|\,|\hat{\mathbf{x}}|\|_\infty}{\|\hat{\mathbf{x}}\|_\infty}$. **51.1**

Skeel matrix condition number (of matrix A): $\operatorname{cond}(A) = \|\,|A^{-1}|\,|A|\,\|_\infty$. **51.1**

skew-Hermitian (matrix): A real or complex matrix equal to the negative of its conjugate transpose. **1.2**, **8.2**

skew-symmetric (matrix): A matrix equal to the negative of its transpose. **1.2**

skew-symmetric (d-hypermatrix): A hypermatrix equal to $\operatorname{sgn}(\pi)$ times its π-transpose for all permutations $\pi \in S_d$. **15.1**

slice (of a 3-hypermatrix): A matrix made from a 3-hypermatrix holding one index constant. **15.1**

Smith invariant factors (of $A \in F^{n\times n}$): The nonconstant polynomials on the diagonal of the Smith normal form of $xI - A$. **6.6**

Smith normal form (of $M \in F[x]^{n\times n}$): The Smith normal matrix obtained from M by elementary row and column operations. **6.6**

Smith normal form (over GCD domain $\mathbb{D}_g$): Matrix $B \in \mathbb{D}_g^{m\times n}$ is in Smith normal form if $B = \operatorname{diag}(b_1, ..., b_r, 0, ..., 0)$, $b_i \neq 0$ for $i = 1, \ldots, r$ and $b_{i-1}|b_i$ for $i = 2, \ldots, r$. **32.2**

Smith normal matrix (in $F[x]^{n\times n}$): A diagonal matrix $\operatorname{diag}(1, \ldots, 1, a_1(x), \ldots, a_s(x), 0, \ldots, 0)$, where the $a_i(x)$ are monic nonconstant polynomials such that $a_i(x)$ divides $a_{i+1}(x)$ for $i = 1, \ldots, s-1$. **6.6**

SNS: See *sign nonsingular.*

S^{2}NS: See *strong sign nonsingular.*

solution: An ordered tuple of scalars that when assigned to the variables satisfies a system of linear equations. **1.4**

solution set: The set of all solutions to a system of linear equations. **1.4**

span, Span (noun): The set of all linear combinations of the vectors in a set. **2.1**

span, spans (verb): A set $S \subseteq V$ spans V if $V = \operatorname{Span}(S)$. **2.1**

spanning subgraph (of connected graph (V, E)): A connected subgraph (V', E') with $V' = V$. **39.1**

spanning tree (of a connected graph): A spanning subgraph that is a tree. **39.1**

spark (of set of vectors S): See *girth.*

sparse (matrix A): The meaning depends on the chapter. Substantial savings in either operations or storage can be achieved when the zero elements of A are exploited during the application of Gaussian elimination to A. **53.2** A large fraction of the entries of A are zeros. **43**

sparse approximate inverse (of matrix A): A sparse matrix M^{-1} constructed to approximate A^{-1}. **54.1**

sparsity pattern: See *sparsity structure.*

sparsity structure (of matrix A): The set of indices of nonzero elements of A. **53.3**

special linear group (of order n over F): The subgroup of the general linear group consisting of all matrices that have determinant 1. **31.2**, **84.1**

spectral absolute value (of complex matrix A): $(A^*A)^{1/2}$. **24.1**

spectral norm (of complex matrix A): $\|A\|_2 = \sqrt{\rho(A^*A)} = \max\{\|A\mathbf{v}\|_2 : \|\mathbf{v}\|_2 = 1\} =$ the largest singular value of A. **8.1**, **50.3**

spectral projector (of $A \in \mathbb{C}^{n\times n}$): A matrix $P \in \mathbb{C}^{n\times n}$ such that $P^2 = P$ and $PA = AP$. **20.1**

spectral radius (of $A \in \mathbb{C}^{n\times n}$): $\max\{|\lambda| : \lambda$ an eigenvalue of $A\}$. **4.4**

spectral representation (of $A \in \mathbb{C}^{n\times n}$): A decomposition of the form $A = P_1A_1P_1 + P_2AP_2 + \cdots + P_mAP_m$, where the P_i are spectral projectors of A and $P_iP_j = 0$ for $i \neq j$. **20.1**

K-spectral set (of bounded linear operator A in a Hilbert space): The set X is a K-spectral set for A if the spectrum of A is included in X and the inequality $\|f(A)\| \leq K\|f\|_X$ holds for every bounded rational function f on X. **37.2**

spectral set (of bounded linear operator A in a Hilbert space): The set $X \subseteq \mathbb{C}$ is a **spectral** set for A if it is a K-spectral set with $K = 1$. **37.2**

spectrally arbitrary pattern (SAP): A sign pattern A of size n such that every monic real polynomial of degree n can be achieved as the characteristic polynomial of some matrix $B \in Q(A)$. **42.6**

spectrum (of a matrix): The multiset of all eigenvalues of a matrix, each eigenvalue appearing with its algebraic multiplicity. **4.4**

spectrum (of a graph): The spectrum of its adjacency matrix. **39.3**

speed (of a processor): The number of floating-point operations per second (flops). **55.9**

splitting: See *preconditioner.*

SPO: See *sign potentially orthogonal.*

square matrix: The number of columns is the same as the number of rows. **1.2**

square root (of a square complex matrix A): A matrix B such that $B^2 = A$. **17.5** (See also *principal square root, PSD square root*)

squared normal (square complex matrix A): A^2 is normal. **7.2**

stable (algorithm): See *numerically stable.*

stable matrix: Either positive stable or negative stable, depending on section; positive in Section **10.5** and Section **26.2**.

standard basis (for F^n or $F^{m\times n}$): The set of vectors or matrices having one entry equal to 1 and all other entries equal to 0. **2.1**

standard basis (for vector space of hypermatrices): The set of hypermatrices having one entry equal to 1 and all other entries equal to 0. **15.1**

standard-conforming (floating point system): Conforming to IEEE standard. **50.6**

standard inner product (in $\mathbb{R}^n$ (or $\mathbb{C}^n$)): $\langle \mathbf{u}, \mathbf{v} \rangle = \mathbf{u}^T\mathbf{v}$ ($\langle \mathbf{u}, \mathbf{v} \rangle = \mathbf{v}^*\mathbf{u}$). **5.1**

standard linear preserver problem: A linear preserver problem where the preservers take one of the standard forms. **30.2**

(R, c, f)-**standard map**: For $A \in F^{n\times n}$, $\phi(A) = cRAR^{-1} + f(A)I$, or $\phi(A) = cRA^TR^{-1} + f(A)I$. R invertible, c nonzero, f a linear functional. **30.2**

(R, S)-**standard map**: For $A \in F^{m\times n}$, $\phi(A) = RAS$, or $m = n$ and $\phi(A) = RA^TS$. R and S must be invertible and may be required to satisfy some additional assumptions. **30.2**

standard matrix (of transformation $T : F^n \to F^m$): The matrix of T with respect to the standard bases for F^n, F^m. **3.3**

state (of $n \times n$ stochastic matrix P): An index $i \in \{1, \dots, n\}$. **10.4**

stationary distribution (of stochastic matrix P): Nonnegative vector π that satisfies $\pi^T\mathbf{1} = \mathbf{1}$ and $\pi^TP = \pi^T$. **10.4**

Stein (matrix) equation: A linear matrix equation of the form $X - AXB - Q = 0$ where $A \in \mathbb{C}^{m\times m},\ B \in \mathbb{C}^{n\times n},\ Q, X \in \mathbb{C}^{m\times n}$. **19.2**

Stein type displacement equation: An equation of the form $\Delta(A) = XY^*$ where $A \in \mathbb{C}^{m\times n}$, Δ is a Stein type displacement operator, $X \in \mathbb{C}^{m\times r}$, and $Y \in \mathbb{C}^{n\times r}$ with $r = \text{rank}(\Delta(A))$. **62.1**

Stein type displacement operator: An operator $\Delta\colon \mathbb{C}^{m\times n} \to \mathbb{C}^{m\times n}$ of the form $\Delta(A) = A - GAH^*$. **62.1**

k-**step Arnoldi factorization**: See *Arnoldi factorization.*

stochastic (square nonnegative matrix P): Same as row-stochastic; the sum of the entries in each row is 1. **10.4**

stopping (matrix): A transient substochastic matrix. **10.4**

strict column signing (of (real or sign pattern) matrix A): AD where D is a strict signing. **42.3**

strict row signing (of (real or sign pattern) matrix A): DA where D is a strict signing. **42.3**

strict signing: A signing where all the diagonal entries are nonzero. **42.3**

strictly block lower triangular (matrix A): A^T is strictly block upper triangular. **11.3**

strictly block upper triangular (matrix): A block upper triangular matrix in which all the diagonal blocks are 0. **11.3**

strictly copositive (matrix A): $\mathbf{x}^T A\mathbf{x} > 0$ for all $\mathbf{x} \geq 0$ and $\mathbf{x} \neq 0$. **49.6**

strictly diagonally dominant ($n \times n$ complex matrix A): $|a_{ii}| > \sum_{j=1,j\neq i}^{n} |a_{ij}|$ for $i = 1, \ldots, n$. **10.5**

strictly equivalent (pencils $A - xB$ and $C - xD$): There exist nonsingular matrices S_1 and S_2 such that $C - \lambda D = S_1(A - \lambda B)S_2$ for all $\lambda \in \mathbb{C}$. **56.1**

strictly equivalent (pencils $A(x), C(x) \in \mathbb{D}[x]^{m\times n}$): $C(x) = QA(x)P$ for some $\mathbb{D}$-invertible matrices P, Q. **32.4**

strictly lower triangular (matrix A): A^T is strictly upper triangular. **11.2**

strictly upper triangular (matrix): A matrix such that every entry having row number greater than or equal to column number is zero. **11.2**

strictly unitarily equivalent (pencils $A - xB$ and $C - xD$): Strictly equivalent pencils in which S_1, S_2 can be taken unitary. **56.1**

Strong Arnold Hypothesis: Satisfied by a real symmetric matrix M provided there does not exist a real symmetric nonzero matrix X such that $MX = \mathbf{0}$, $M \circ X = \mathbf{0}$, $I \circ X = \mathbf{0}$. **39.5**

strong combinatorial invariant (of a matrix): A quantity or property that does not change when the rows and/or columns are permuted. **38.1**

(strong) product (of simple graphs $G = (V, E), G' = (V', E')$): The simple graph with vertex set $V \times V'$, where two distinct vertices are adjacent whenever in both coordinate places the vertices are adjacent or equal in the corresponding graph. **39.1**

strong sign nonsingular ($\mathbf{S^2NS}$) (square sign pattern A): A is an SNS-pattern such that the matrix B^{-1} is in the same sign pattern class for all $B \in Q(A)$. **42.2**

strongly backward stable (eigensolver): Instead of the exact eigenpair $(\lambda, \mathbf{x})$ of matrix $A \in \mathcal{C}$, an approximate eigenpair is computed with a small structured backward error $\eta^{\mathcal{C}}(\tilde{\lambda}, \tilde{\mathbf{x}})$, that is, it is backward stable and $(A + E) \in \mathcal{C}$. **63.2**

strongly connected: A digraph whose vertices all lie in a single access equivalence class. **10.1, 40.5**

strongly connected components (of a digraph): The subdigraphs induced by the access equivalence classes. **40.5**

strongly inertia preserving (real square matrix A): The inertia of AD is equal to the inertia of D for every real diagonal matrix D. **26.5**

strongly nonsingular (square matrix): All its principal submatrices are nonsingular. **61.6**

ϕ **strongly preserves** (subset of matrices $\mathcal{M}$): $\phi(\mathcal{M}) = \mathcal{M}$. **30.1**

ϕ **strongly preserves** (relation $\sim$ on matrix subspace $\mathcal{V}$): For every pair $A, B \in \mathcal{V}$, we have $\phi(A) \sim \phi(B)$ if and only if $A \sim B$. **30.1**

strongly regular: A simple graph with parameters (n, k, λ, μ) that has n vertices, is k-regular with $1 \leq k \leq n-2$, every two adjacent vertices have exactly λ common neighbors, and every two distinct nonadjacent vertices have exactly μ common neighbors. **39.2**

strongly stable: See *additive D-stable.*

structured componentwise backward error (of approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ for matrix $A \in \mathcal{C}$): $\omega^{\mathcal{C}}(\tilde{\lambda}, \tilde{\mathbf{x}}) = \min\{\max_{i,j} |e_{ij}| : (A + E)\tilde{\mathbf{x}} = \tilde{\lambda}\tilde{\mathbf{x}}, (A + E) \in \mathcal{C}\}$. **63.2**

structured eigenvalue condition number (of eigenvalue λ of matrix $A \in \mathcal{C}$): $\mathrm{cond}^{\mathcal{C}}(A, \lambda) = \lim_{\epsilon\to 0} \sup_{||E||\leq\epsilon}\{\frac{|\tilde{\lambda}-\lambda|}{\epsilon} : \tilde{\lambda} \in \sigma(A + E), A + E \in \mathcal{C}\}$. **63.4**

structured normwise backward error (of an approximate eigenpair $(\tilde{\lambda}, \tilde{\mathbf{x}})$ for matrix $A \in \mathcal{C}$): $\eta^{\mathcal{C}}(\tilde{\lambda}, \tilde{\mathbf{x}}) = \min\{||E|| : (A + E)\tilde{\mathbf{x}} = \tilde{\lambda}\tilde{\mathbf{x}}, (A + E) \in \mathcal{C}\}$. **63.2**

subdigraph (of digraph $\Gamma = (V, E)$): A digraph $\Gamma' = (V', E')$ with $V' \subseteq V$ and $E' \subseteq E$. **40.1**

subgraph (of graph (V, E)): A graph $G' = (V', E')$ with $V' \subseteq V$ and $E' \subseteq E$. **39.1**

subgraph (of weighted graph G): A graph H on a subset of the vertices of G with weight function satisfying $w_H(v, w) \leq w_G(v, w)$ for all vertices of H. **47.4**

submatrix: A matrix lying in certain rows and columns of a given matrix. **1.2**, **11.1**

$\mathbb{D}$-submodule: A nonempty set $\mathbf{N} \subseteq \mathbf{M}$ that is closed under addition and multiplication by ($\mathbb{D}$) scalars. **32.3**

submultiplicative (norm $\|\cdot\|$ on $\mathbb{C}^{n\times n}$): A vector norm satisfying $\|AB\| \leq \|A\|\|B\|$ for all $A, B \in \mathbb{C}^{n\times n}$ (satisfies the conditions of a matrix norm except not required to be part of a family). **25.4**

subordinate (matrix norm): See *induced norm.*

(k-th)-subpermanent sum (of matrix A): The sum of the permanents of all order k submatrices of A. **43.7**

subpattern (of a sign pattern): A sign pattern obtained by replacing some (possibly none) of the nonzero entries with 0. **42.1**

subspace: Subset of a vector space V that is itself a vector space under the operations of V. **1.1**

subspace iteration: See *orthogonal iteration.*

substochastic (square nonnegative matrix P): The sum of the entries in each row is ≤ 1. **10.4**

subtournament: A subdigraph of a tournament that is itself a tournament. **45.1**

subtractive cancellation of significant digits: Occurs in floating point sums when the relative error in the rounding-error-corrupted approximate sum is substantially greater than the relative error in the summands. **50.6**

sum (of subspaces): $W_1 + \cdots + W_k = \{\mathbf{w}_1 + \cdots + \mathbf{w}_k \ : \mathbf{w}_i \in W_i\}$. **2.3**

sum norm: See *1-norm.*

sup-norm: See ∞*-norm.*

support (of rectangular matrix A or vector): The set of indices ij with $a_{ij} \neq 0$. **10.6**

support line (of convex set S): A line ℓ that intersects ∂S such that S lies entirely within one of the closed half-planes determined by ℓ. **25.2**

G **supports rank decompositions**: Each matrix $A \in \mathcal{M}(G)$ is the sum of rank A matrices in $\mathcal{M}(G)$ each having rank 1 (also a variant for signed bipartite graphs). **41.3**

surjective: See *onto.*

SVD: See *singular value decomposition.*

switching equivalent: A simple graph that can be obtained from another simple graph by a Seidel switching. **39.4**

Sylvester (matrix) equation: A linear matrix equation of the form $AX + XB - Q = 0$, where $A \in \mathbb{C}^{m\times m}$, $B \in \mathbb{C}^{n\times n}$, $Q \in \mathbb{C}^{m\times n}$, and $X \in \mathbb{C}^{m\times n}$. **19.2**

Sylvester operator (for $L \in \mathbb{C}^{\ell\times\ell}$ and $M \in \mathbb{C}^{m\times m}$): The linear operator on $\mathbb{C}^{m\times\ell}$ defined by $Q \mapsto QL - MQ$. **20.3**

Sylvester type displacement equation: An equation of the form $\Delta(A) = XY^*$ where $A \in \mathbb{C}^{m\times n}$, Δ is a Sylvester type displacement operator, $X \in \mathbb{C}^{m\times r}$, and $Y \in \mathbb{C}^{n\times r}$ with $r = \operatorname{rank}(\Delta(A))$. **62.1**

Sylvester type displacement operator: An operator $\Delta\colon \mathbb{C}^{m\times n} \to \mathbb{C}^{m\times n}$ of the form $\Delta(A) = EA - AH^*$. **62.1**

Sym: The map $\operatorname{Sym}(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k) = \frac{1}{m!}\sum_{\pi\in S_m} \mathbf{v}_{\pi(1)} \otimes \cdots \otimes \mathbf{v}_{\pi(k)}$. **14.6**

sym multiplication: $(\mathbf{v}_1 \vee \cdots \vee \mathbf{v}_p) \vee (\mathbf{v}_{p+1} \vee \cdots \vee \mathbf{v}_{p+q}) = \mathbf{v}_1 \vee \cdots \vee \mathbf{v}_{p+q}$. **14.7**

symbol (of a family of Toeplitz matrices): The function $a(z) = \sum a_k z^k$ where the a_k are the constants of the Toeplitz matrices. **23.2**

symbol curve (of a Toeplitz family): The image of the complex unit circle under the symbol. **23.2**

symmetric (bilinear form f): $f(\mathbf{u}, \mathbf{v}) = f(\mathbf{v}, \mathbf{u})$ for all $\mathbf{u}, \mathbf{v} \in V$. **13.2**

symmetric (digraph $\Gamma = (V, E)$): $(i, j) \in E$ implies $(j, i) \in E$ for all $i, j \in V$. **49.1**

symmetric (form): A multilinear form that is a symmetric map. **14.5**

symmetric (d-hypermatrix): A hypermatrix equal to its π-transpose for all permutations $\pi \in S_d$. **15.1**

symmetric (map $\psi \in L^m(V;U)$): $\psi(\mathbf{v}_{\pi(1)}, \ldots, \mathbf{v}_{\pi(m)}) = \psi(\mathbf{v}_1, \ldots, \mathbf{v}_m)$, for all permutations π. **14.5**

symmetric (matrix): A matrix equal to its transpose. **1.2**

symmetric (d-tensor): A tensor invariant under the action of π for all permutations $\pi \in S_d$. **15.2**

symmetric algebra (on vector space V): $\bigvee V = \bigoplus_{k\in\mathbb{N}} \left(\bigvee^k V\right)$ with sym multiplication. **14.9**

symmetric inertia set (of symmetric sign pattern A): $\text{in}(A) = \{\text{in}(B) : B = B^T$ and $B \in Q(A)\}$. **42.6**

symmetric matrices associated with graph G: See *set of symmetric matrices associated with graph G.*

symmetric maximal rank (of symmetric sign pattern A): $\max\{\text{rank}\, B : B^T = B$ and $B \in Q(A)\}$. **42.6**

symmetric minimal rank (of symmetric sign pattern A): $\min\{\text{rank}\, B : B^T = B$ and $B \in Q(A)\}$. **42.6**

symmetric power (of a vector space): See *symmetric space.*

symmetric product (of vectors $\mathbf{v}_1, \ldots, \mathbf{v}_m$): $\mathbf{v}_1 \vee \cdots \vee \mathbf{v}_m = m!\text{Sym}(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_k)$. **14.6**

symmetric rank revealing decomposition (SRRD) (of symmetric real matrix H): A decomposition $H = XDX^T$, where D is diagonal and X is a full column rank well-conditioned matrix. **59.5**

symmetric space (of vector space V): $\bigvee^m V = \text{Sym}(\bigotimes^m V)$. **14.6**

symmetric scaling (of a matrix): A scaling where $D_1 = D_2$. **10.6**, **38.6**

symplectic (matrix): A matrix $M \in \mathbb{R}^{2n\times 2n}$ such that $MJM^T = \text{J}$ where $\text{J} = \left[\begin{smallmatrix} 0 & I \\ -I & 0 \end{smallmatrix}\right]$. **63.1**

system of distinct representatives (SDR): For the finite sets $S_1, S_2, \ldots, S_n$, a choice of $x_1, x_2, \ldots, x_n$ with the properties that $x_i \in S_i$ for each i and $x_i \neq x_j$ whenever $i \neq j$. **43.3**

system of linear equations: A set of one or more linear equations in the same variables. **1.4**

T

tensor: An element of a tensor product (space). **14.2, 15.2**

tensor algebra (on vector space V): $\bigotimes V = \bigoplus_{k\in\mathbb{N}} \left(\bigotimes^k V\right)$. **14.9**

tensor multiplication: $(\mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_p) \otimes (\mathbf{v}_{p+1} \otimes \cdots \otimes \mathbf{v}_{p+q}) = \mathbf{v}_1 \otimes \cdots \otimes \mathbf{v}_{p+q}$. **14.7**

tensor power: A tensor product of copies of one vector space. **14.2**

tensor product (of matrices): See *Kronecker product.*

tensor product (space) (of vector spaces $V_1, \ldots, V_m$): A multilinear map satisfying a universal factorization property. **14.2**, **15.2**

term rank (of $(0,1)$-matrix A): The largest size of a collection of 1s of A with no two 1s in the same line. **38.1**

term rank (of sign pattern A): The maximum number of nonzero entries of A no two of which are in the same row or the same column. **42.6**

tight sign-central: A sign-central pattern A for which the Hadamard product of any two columns contains a negative element. **42.10**

TN: See *totally nonnegative.*

Toeplitz (matrix): A matrix whose entries are constant along each sub- and super-diagonal, i.e., the value of the i,j-entry is the constant a_k whenever $i - j = k$. **23.2**, **22.2**

Toeplitz Bezoutian: A matrix defined from two vectors (need not be Toeplitz). **22.2**

Toeplitz inverse eigenvalue problem (ToIEP): Given $\lambda_1, \ldots, \lambda_n \in \mathbb{R}$, find $\mathbf{c} = [c_1, \ldots, c_n]^T \in \mathbb{R}^n$ such that $\left[\, t_{ij} \,\right]_{i,j=1}^n$ with $t_{ij} = c_{|i-j|+1}$ has spectrum $\{\lambda_1, \ldots, \lambda_n\}$. **28.9**

Toepliz-like with displacement rank r (matrix A): A satisfies a displacement equation of the form $A - Z_m A Z_n^* = XY^*$ or $Z_{1,m}^* A - A Z_{\delta,n}^* = XY^*$, where $X \in \mathbb{C}^{m\times r}$ and $Y \in \mathbb{C}^{n\times r}$. **62.1**

ToIEP: See *Toeplitz inverse eigenvalue problem.*

total least squares problem: See Section **52.1**.

total signed compound (TSC) (sign patterns): Every square submatrix of every matrix $A \in Q(S)$ is either sign nonsingular or sign singular. **59.3**

total support: An $n \times n$ $(0,1)$-matrix A has total support if $A \neq \mathbf{0}$ and each 1 of A is on a diagonal of A. **38.2**

totally nonnegative (real matrix A): Every minor is nonnegative. **29.1**

totally nonpositive (real matrix A): Every minor is nonpositive. **49.13**

totally positive (real matrix A): Every minor is positive. **29.1**

totally unimodular (real matrix A): All minors of A are from $\{-1, 0, 1\}$). **59.3**

tournament: A simple directed graph in which exactly one of the two arcs (i, j) and (j, i) is present for each pair of distinct vertices i and j (same as digraph of a tournament matrix). **38.5**, **45.1**

tournament matrix: A (0,1)-matrix with 0 diagonal and exactly one of a_{ij}, a_{ji} equal to 1 for all $i \neq j$. **38.5**

TP: See *totally positive.*

trace: The sum of all the diagonal entries of the matrix. **1.2**

trace-minimal (graph G in a family $\mathcal{F}$ of graphs): The trace-sequence of the adjacency matrix of G is least in lexicographic order among all graphs in $\mathcal{F}$. **44.7**

trace norm (of $A \in \mathbb{C}^{m\times n}$): The sum of the singular values of A. **24.3**

trace-sequence (of $n \times n$ matrix A): $(\mathrm{tr}(A), \mathrm{tr}(A^2), \cdots, \mathrm{tr}(A^n))$. **44.7**

transient class (of stochastic matrix P): An access equivalence class of P that is not ergodic. **10.4**

transient matrix: See convergent.

transient state: A state in a transient class. **10.4**

transition matrix: See *change-of-basis matrix.*

transitive tournament: A tournament in which ($i \to j$ and $j \to k$) implies $i \to k$. **45.1**

transitive tournament matrix A: $a_{ij} = a_{jk} = 1$ implies $a_{ik} = 1$. **38.5**

transpose (of a linear transformation): A specific linear transformation from the dual of the codomain to the dual of the domain. **3.8**

transpose (of $m \times n$ matrix A): The $n \times m$ matrix $B = [b_{ij}]$ where $b_{ij} = a_{ji}$. **1.2**

π-**transpose** (of d-hypermatrix A): A permutation of the entries of A by permutation $\pi \in S_d$ acting on the entry subscripts. **15.1**

transposition: A 2-cycle. **Preliminaries**

tree (digraph): A digraph whose associated graph is a tree. **40.1**

tree (graph): A connected graph with no cycles. **39.1**

k-**tree**: A simple graph constructed inductively starting with a complete graph on $k + 1$ vertices and connecting each new vertex to the vertices of an existing clique on k vertices. **46.1**

tree sign pattern (t.s.p.): A combinatorially symmetric sign pattern matrix whose graph (suppressing loops) is a tree. **42.5**

tree-width (of a simple graph G): The minimum k such that G is a partial k-tree. **46.1**

triangular (matrix): Upper or lower triangular. **11.2**

triangular property (of class of matrices X): Whenever A is a block triangular matrix and every diagonal block is an X-matrix, then A is an X matrix. **49.1**

triangular system: A linear system $T\mathbf{x} = \mathbf{b}$ where T is a triangular matrix. **51.2**

triangular totally positive (ΔTP): A triangular matrix all of whose nontrivial minors are positive. **29.2**

tridiagonal matrix: A square matrix A such that $a_{ij} = 0$ if $|i - j| > 1$.
trivial face (F of cone K): $F = \{0\}$ or $F = K$. **36.1**
trivial linear combination: A linear combination in which all the scalar coefficients are 0 (or over the empty set). **2.1**
truncation error: The error made by replacing an infinite process by a finite process. **50.6**
TSC: See *total signed compound.*
t.s.p. See *tree sign pattern.*
two-sided Lanczos algorithm: See Section **54.3**.
type I (tree): Has exactly one characteristic vertex. **48.3**
type II (tree): Has two characteristic vertices. **48.3**

U

UFD: See *unique factorization domain.*
u.i.: See *unitarily invariant.*
underflow: $\mathrm{fl}(x) = 0$ for $x \neq 0$. **50.6**
unicyclic: A graph containing precisely one cycle. **48.2**
unimodular (matrix over a domain): See $\mathbb{D}$-*invertible.*
unimodular (matrix polynomial $P(x)$): $\det P(x)$ is a nonzero constant independent of x. **39.1**
union (of two graphs $G = (V, E)$ and $G' = (V', E')$): The graph with vertex set $V \cup V'$, and edge (multi)set $E \cup E'$. **39.1**
unique factorization domain (UFD): Any nonzero, nonunit element a can be factored as a product of irreducible elements $a = p_1 \cdots p_r$, and this factorization is unique up to order and unit factors. **32.1**
unisigned (real or sign pattern vector): Not balanced. **42.3**
unit (in a domain): An element a such that a divides 1. **32.1**
unit lower triangular matrix: A lower triangular matrix such that all diagonal entries are equal to one. **1.2**
unit round: $u = \inf\{\delta > 0 \mid \mathrm{fl}(1 + \delta) > 1\}$. **50.6**
unit upper triangular matrix: An upper triangular matrix such that all diagonal entries are equal to one. **1.2**
unit vector: A vector of length 1. **5.1**
unital (linear map $\phi : \mathbb{C}^{n\times n} \to \mathbb{C}^{m\times m}$): $\phi(I_n) = I_m$. **25.7**
unitarily congruent (matrices A and B): There exists a unitary matrix U such that $A = UBU^T$. **7.3**
unitarily *congruent (matrices A and B): There exists a unitary matrix U such that $A = UBU^*$. **7.2**
unitarily equivalent (matrices A and B): There exist unitary matrices V and W such that $A = VBW$. **7.1**
unitarily invariant (vector norm $\|\cdot\|$ on $\mathbb{C}^{m\times n}$): $\|A\| = \|UAV\|$ for any unitary $U \in \mathbb{C}^{m\times m}$ and $V \in \mathbb{C}^{n\times n}$ and any $A \in \mathbb{C}^{m\times n}$. **24.3**
unitarily similar (matrices A and B): There exists a unitary matrix U such that $B = U^*AU$. **8.1**
unitarily similarity invariant (vector norm $\|\cdot\|$ on $\mathbb{C}^{n\times n}$): $\|U^*AU\| = \|A\|$ for all $A \in \mathbb{C}^{n\times n}$ and unitary $U \in \mathbb{C}^{n\times n}$. **25.4**
unitarily wild: A matrix problem that contains the problem of classifying arbitrary square complex matrices under unitary similarity. **7.2**
unitary matrix: A matrix U such that $U^*U = I$. **5.2**, **8.1**
unknown vector: The vector of variables of a system of linear equations. **1.4**

unreduced upper Hessenberg (matrix): An upper Hessenberg matrix A such that $a_{j+1,j} \neq 0$ for $j = 1, \ldots, n-1$. **56.2**

unstable (algorithm): See *numerically unstable.*

updating (QR factorization): See Section **52.7**.

upper Hessenberg (matrix A): $a_{ij} = 0$, for all $i \geq j+2$, $1 \leq i, j \leq n$. **11.2**, **56.2**

upper triangular (pencil $A - xB$): Both A and B are upper triangular. **56.1**

upper triangular matrix: A matrix such that every entry having row number greater than column number is zero. **1.2**, **11.2**

V

(v, k, λ)-design: See *2-design.*

valency: See *degree.*

Vandermonde matrix: A matrix having each row equal to successive powers of a number. **22.4**

Vandermonde-like with displacement rank r (matrix A): A satisfies a displacement equation of the form $D_{\mathbf{v}}A - AZ_{\delta,n} = XY^*$ where $X \in \mathbb{C}^{m\times r}$ and $Y \in \mathbb{C}^{n\times r}$. **62.1**

variables (of a linear equation): The unknowns. **1.4**

vec-function (of matrix A): The vector formed by stacking the columns of A on top of each other in their natural order. **11.4**

vector: An element of a vector space. **1.1**

vector norm: A real-valued function $\|\cdot\|$ on $\mathbb{R}^n$ or $\mathbb{C}^n$ such that for all vectors $\mathbf{x}$, $\mathbf{y}$ and all scalars α: (1) $\|\mathbf{x}\| \geq 0$, and $\|\mathbf{x}\| = 0$ implies $\mathbf{0}$; (2) $\|\alpha\mathbf{x}\| = |\alpha|\|\mathbf{x}\|$; (3) $\|\mathbf{x}+\mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$. **50.1**

vector seminorm: A real-valued function $\|\cdot\|$ on $\mathbb{R}^n$ or $\mathbb{C}^n$ such that for all vectors $\mathbf{x}$, $\mathbf{y}$ and all scalars α: (1) $\|\mathbf{x}\| \geq 0$; (2) $\|\alpha\mathbf{x}\| = |\alpha|\|\mathbf{x}\|$; (3) $\|\mathbf{x}+\mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$. **50.2**

vector space (over field F): A nonempty set V with two operations, addition and scalar multiplication, such that V is an abelian group under addition, scalar multiplication distributes over addition, scalar multiplication is associative, and the multiplicative identity of F acts as the identity on V. **1.1**

vertex: An element of the vertex set of a graph or digraph. **39.1**, **40.1**

vertex coloring (of a graph): A partition of the vertex set of a graph into cocliques. **39.5**

vertex connectivity (of simple graph G): The smallest number k such that there is a set of vertices S, with $|S| = k$, for which $G - S$ is disconnected. **46.1**

vertex-edge incidence matrix: See *incidence matrix.* **41.1**

vertex independence number: The largest order of a coclique in G. **39.5**

vertices: Plural of *vertex.*

Volterra–Lyapunov stable: See *Lyapunov diagonally stable.*

W

walk (in a digraph): A sequence of arcs $(v_0, v_1), (v_1, v_2), \ldots, (v_{k-1}, v_k)$ (the vertices need not be distinct). **40.1**

walk (in a graph): An alternating sequence $(v_{i_0}, e_{i_1}, v_{i_1}, e_{i_2}, ..., e_{i_\ell}, v_{i_\ell})$ of vertices and edges, not necessarily distinct, such that $v_{i_{j-1}}$ and v_{i_j} are endpoints of e_{i_j} for $j = 1, \ldots, \ell$. **39.1**

walk product: $\prod_{j=1}^{k} a_{v_{j-1},v_j}$ where A is a square matrix and $(v_0, v_1), (v_1, v_2), \ldots, (v_{k-1}, v_k)$ is a walk in the digraph of A. **40.3**

walk-regular (graph): For every vertex v the number of walks from v to v of length ℓ, depends only on ℓ (not on v). **39.2**

weak combinatorial invariant (of a matrix): A quantity or property that does not change when the rows and columns are simultaneously permuted (by the same permutation). **38.1**

weakly majorizes: Real sequence α weakly majorizes β if for all k, the sum of the first k entries of α in decreasing order is $\geq$ the sum of the first k entries of β in decreasing order. **Preliminaries**

weakly numerically stable (algorithm): The magnitude of the forward error is roughly the same as the magnitude of the error induced by perturbing the data by small multiples of the unit round. **50.8**

weakly sign symmetric (square matrix A): $\det A[\alpha,\beta] \det A[\beta,\alpha] \geq 0$, $\forall \alpha,\beta \subseteq \{1,\ldots,n\}$, $|\alpha| = |\beta| = |\alpha \cap \beta| + 1$. **26.2**

weakly unitarily invariant: See *unitarily similarity invariant.*

weight function: A function from the edges or arcs of a graph. bipartite graph, or digraph to $\mathbb{R}^+$. **47.1, 41.1, 40.1**

weighted bigraph (of matrix A): The bigraph of A with the weight of $\{i, j'\} = a_{ij}$. **41.2**

weighted bipartite graph: A simple bipartite graph with a weight function on the edges. **41.1**

weighted digraph: A digraph with a weight function on the arcs. **40.1**

weighted graph: A graph (that does not allow multiple edges but may allow loops) with a weight function. **47.1, 48.4**

weighted least squares problem: See Section **52.1**.

well-conditioned (input $\mathbf{z}$ for P): Small relative perturbations of $\mathbf{z}$ cause small relative perturbations of $P(\mathbf{z})$. **50.4**

Weyr block: $W_A(\lambda)$, an upper triangular matrix of special form determined by the Weyr characteristic of A, with λ on the diagonal. **6.4**

Weyr canonical form (of matrix A): A direct sum of the Weyr blocks of A (over the distinct eigenvalues of A). **6.4**

Weyr characteristic: $w_k(A,\lambda) = \text{rank}(A - \lambda I)^{k-1} - \text{rank}(A - \lambda I)^k$. **6.4**

Weyr matrix: A direct sum of of Weyr blocks with distinct eigenvalues. **6.4**

Wiener vertex: See *Parter–Wiener vertex.*

Wilkinson's shift: The shift μ is the eigenvalue of the bottom right 2×2 submatrix of T which is closer to $t_{n,n}$. **55.3**

Z

Z-matrix (square real matrix): All off-diagonal elements are nonpositive. **10.5**, **26.2**

zero completion (of a partial matrix): Obtained by setting all unspecified (off-diagonal) entries to 0 (partial matrix must have all diagonal entries specified). **49.7**

zero divisor (in ring R): A nonzero element $a \in R$ such that there exists a nonzero $b \in R$ with $ab = 0$ or $ba = 0$. **Preliminaries**

zero forcing number (of a simple graph): The minimum number of vertices in a zero forcing set. **46.4**

zero forcing set (of a simple graph): A subset of vertices such that if these vertices are colored black and the remaining vertices are colored white, it is possible to color all the vertices black by the color change rule. **46.4**

zero-free diagonal (property of matrix A): All the diagonal elements of A are nonzero. **53.3**

zero line (in a matrix): A line of all zeros. **38.1**

zero matrix: A matrix with all entries equal to zero. **1.2**

(zero) pattern (of a matrix): See *pattern.*

zero pattern (of sign pattern A): The $(0,+)$-pattern obtained by replacing each $-$ entry in A by a $+$. **42.2**

zero transformation: A linear transformation that maps every vector to zero. **3.1**

DISCRETE MATHEMATICS AND ITS APPLICATIONS

Series Editor KENNETH H. ROSEN

With a substantial amount of new material, the **Handbook of Linear Algebra, Second Edition** provides comprehensive coverage of linear algebra concepts, applications, and computational software packages in an easy-to-use format. It guides you from the very elementary aspects of the subject to the frontiers of current research. Along with revisions and updates throughout, the second edition of this bestseller includes 20 new chapters.

New to the Second Edition

- Separate chapters on Schur complements, additional types of canonical forms, tensors, matrix polynomials, matrix equations, special types of matrices, generalized inverses, matrices over finite fields, invariant subspaces, representations of quivers, and spectral sets
- New chapters on topics in combinatorial matrix theory and numerical linear algebra
- More chapters on applications of linear algebra, including epidemiology and quantum error correction
- New chapter on using the free and open source software system Sage for linear algebra
- Additional sections in the chapters on sign pattern matrices and applications to geometry
- Conjectures and open problems in most chapters on advanced topics

Highly praised as a valuable resource for anyone who uses linear algebra, the first edition covered virtually all aspects of linear algebra and its applications. This edition continues to encompass the fundamentals of linear algebra, combinatorial and numerical linear algebra, and applications of linear algebra to various disciplines while also covering up-to-date software packages for linear algebra computations.
